

# PATHOLOGIC BASIS *of* VETERINARY DISEASE

## **1 Chapter 1 Cellular and Tissue Responses to Injury**

RONALD K. MYERS

M. DONALD McGAVIN

### **1.1 INTRODUCTION**

The simple definition that pathology is the study of disease understates the wide range and contributions of this discipline to modern medicine. An understanding of pathology is fundamental to understanding how disease works and consequently how it can be diagnosed, treated, and prevented.

To students of medical science, pathology is the course of study that finally connects the study of normal form and function (histology, anatomy, and physiology) to the study of clinical medicine. Pathology is fundamental to making sense of how the various causes of disease (bacteriologic, virologic, and parasitologic causes, for example) interact with the host and result in clinically identifiable conditions.

Pathology is also an important professional practice that directly supports clinical practice. Diagnostic pathologists, for example, perform postmortem examinations (necropsies), which provide clinicians with essential information on how to manage disease outbreaks in herds and how to improve management of individual cases. Surgical pathologists examine tissue removed from live animals (biopsy) and provide diagnoses that help clinicians treat animals under their care. Toxicologic pathologists test and evaluate the effects and safety of drugs and chemicals in laboratory animals. Clinical pathologists perform tests on blood and other body fluids (hematology and serum chemistry, for example) and examine cells (cytology) to provide detailed and essential information for clinicians. Experimental pathologists study the tissue, cellular, and molecular mechanisms of human and animal diseases in the fields of biomedicine and biomedical engineering.

Pathology is also an experimental science that makes essential contributions to further our understanding of disease mechanisms through use of a tremendous variety of techniques. Advanced methods of cell and molecular biology are used to unravel the complexities of how cells and animals respond to injury, so that deeper understanding of diseases can help improve treatment and prevention.

In summary, pathology is according to one dictionary (Stedman's Medical Dictionary) "the medical science, and specialty practice, concerned with all aspects of disease, but with special reference to the essential nature, causes, and development of abnormal conditions, as well as the structural and functional changes that result from the disease processes."

### **1.2 BASIC TERMINOLOGY**

If pathology is the study of disease, what is disease? A dictionary definition (Dorland's Medical Dictionary) states that disease is "any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown." Disease is not just illness or sickness but includes any departure from normal form (lesions) and function, whether it is clinically apparent or not.

Pathologists study lesions but also the causes (etiologic agents) of the lesions to understand the pathogenesis of a disease. Pathogenesis is the mechanism of how a disease develops from its initiation to its cellular and molecular manifestations. Understanding pathogenesis is essential to understanding how a disease is initiated and progresses,

## Pathologic Basis of Veterinary Disease, 4th Edition

how these changes relate to clinical signs at different stages of the disease, and how appropriate clinical action can be taken.

3

The relationship of pathology to clinical medicine and the use of some of the basic terms discussed previously along with some additional terms are illustrated in the following clinical scenario.

4

In a beef feedlot, several steers and heifers are exhibiting difficult breathing, hunched posture, and depression (clinical signs). Physical examination of some of the infected animals reveals elevated temperatures, pulse rates, and respiration rates. Auscultation of the thorax reveals absence of air movement in the cranial region of the thorax along with some crackles and wheezes in other lung fields. A clinical diagnosis of bronchopneumonia is made. Some of the animals die, and a necropsy (postmortem examination) is done. The cranioventral lobes of the lungs are dark red and firm, with fibrin covering the surface (gross lesions). A gross morphologic diagnosis of severe acute fibrinopurulent cranioventral bronchopneumonia is made. Formalin fixed samples are taken for microscopic examination (histopathology), neutrophilic inflammation of airways and alveoli with fibrin are noted (microscopic lesions), and a histologic morphologic diagnosis of severe acute fibrinopurulent bronchopneumonia is made. Fresh samples of lung are taken for bacterial and viral examination, and *Mannheimia haemolytica* and a bovine herpes virus (etiologic agents or causes) are identified. An etiologic diagnosis of *Mannheimia* bronchopneumonia and a disease diagnosis of “shipping fever pneumonia” are made.

The pathogenesis of the above disease might be stated in an abbreviated form like this:

Various viruses, such as infectious rhinotracheitis virus, and environmental agents, such as dust and noxious gases, disrupt the clearance mechanisms of the airway epithelium allowing opportunistic organisms, such as the bacterium *Mannheimia haemolytica* to colonize and invade the alveoli. Virulence factors of the bacteria, such as endotoxin and various exotoxins, cause necrosis and inflammation, which result in the filling of alveoli and airways with fibrin and neutrophils.

Although the histologic diagnosis of the disease was done by a diagnostic pathologist, the details of this pathogenesis were discovered over time by researchers in many fields, including experimental pathologists.

### 1.3 TYPES OF DIAGNOSIS

Note in the previous scenario that various levels of diagnosis were made. Diagnosis is a concise statement or conclusion concerning the nature, cause, or name of a disease. The accuracy of a diagnosis is limited by the evidence (lesions) available for study. A clinical diagnosis is based on the data obtained from the case history, clinical signs, and physical examination. It often suggests only the system involved, or it provides a list of differential diagnoses. The differential diagnosis (often termed “rule outs” in clinical medicine) is a list of diseases that could account for the evidence or lesions of the case. A clinical pathologic diagnosis is based on changes observed in the chemistry of fluids and the hematology, structure, and function of cells collected from the living patient. A morphologic diagnosis or lesion diagnosis is based on the predominant lesion(s) in the tissue(s) (see [Chapter 3](#) and [Fig. 3-24](#)). It may be macroscopic (gross) or microscopic (histologic) and describes the severity, duration, distribution, location (organ or tissue), and nature (degenerative, inflammatory, neoplastic) of the lesion. An etiologic diagnosis is even more definitive and names the specific cause of the disease. A disease diagnosis is equally specific and states the common name of the disease.

One of the goals in making a diagnosis in a case is to enable a clinician to predict how the disease will progress or resolve. Prognosis is a statement of what the expected outcome of a condition is likely to be. If the lesion is expected to resolve (return to normal) with no expected lasting harm, the prognosis is good or excellent. If the outcome is uncertain—the lesion could resolve or become worse as a result of unforeseen factors—the prognosis is

# Pathologic Basis of Veterinary Disease, 4th Edition

---

guarded. If the animal is not expected to recover from the lesion or disease, the prognosis is grave. Accurate determination of the prognosis demands a thorough understanding of the disease, especially pathogenesis.

As in this book, the study of pathology is often divided into two basic parts: general pathology and pathology of organ systems. General pathology is the study of basic responses of cells and tissues to insults and injuries, irrespective of the organs, systems, or species of animal involved. This area of pathology is one of the most complex and rapidly growing fields in the natural sciences, largely due to the availability and power of new research techniques. General pathology is studied first, so students will have a thorough understanding of the general principles of disease processes that they will encounter repeatedly in the study of diseases of body systems. Pathology of organ systems (sometimes called systemic or special pathology) involves the study of how each organ system reacts to injury associated with specific diseases.

## 1.4 MORPHOLOGIC CHANGES AND HOW THEY ARE DETECTED AND EVALUATED

The study and practice of pathology historically have been based on the macroscopic and microscopic changes that take place in diseased cells, tissues, and organs, that is to say, the morphology of lesions. Consequently, most pathology texts tend to emphasize anatomic pathology. Morphologic techniques remain the cornerstones of pathology, but progress in our deeper understanding of the mechanisms and in the diagnosis of disease rely more and more on techniques derived from cellular and molecular biology.

4  
5

The basic tools for the study and practice of pathology begin with an open and inquiring mind, skills in observation, and careful and consistent postmortem techniques. The diagnosis of many diseases can be accurately accomplished with no more than gross examination of a body. Confirmation of gross lesions and discovery and interpretation of microscopic changes typically involves observation of tissue placed on glass microscope slides. Tissues are first fixed (i.e., preserved) usually in 10% formalin, embedded in blocks of paraffin wax, microtome sectioned to about 5  $\mu$ m thickness, and routinely stained with hematoxylin and eosin (H&E). H&E stained sections are the mainstay of histopathology in both postmortem and surgical pathology, and interpretation of lesions in these specimens can often lead to a final diagnosis. A simplistic explanation of the labeling characteristics of the H&E stain as applied to tissue sections is as follows: Hematoxylin stains nucleic acids (nucleus, ribosomes, mitochondria) blue, whereas eosin stains proteins such as those found intracellularly (e.g., enzymes, actin, and myosin) or those proteins found extracellularly (e.g., collagen and extracellular matrix [ECM]) red or pink.

A variety of ancillary techniques are also used in histopathology. Histochemistry applies a variety of chemical reactions carried out on tissue sections. Glycogen, for example, can be identified in hepatocytes using periodic acid–Schiff (PAS) reaction. Suspected mast cell tumors are routinely stained to demonstrate the metachromatic mast cell granules using toluidine blue or Giemsa stains.

Increasing use in diagnostic laboratories is being made of immunohistochemistry, in which specific antigens are identified in tissue by antibodies linked to a chromogen. Detection of specific intermediate fibers by immunohistochemistry, in tumors for example, can separate malignant striated muscle tumors from other sarcomas. Specific infectious agents, such as the corona virus causing feline infectious peritonitis, can also be identified using immunohistochemistry.

A variety of techniques for identification of molecules or genetic sequences are now in use, with more expected. In situ hybridization, in which labeled nucleic acid probes can identify complementary strands of host or microbe DNA or RNA in intact cells and tissues, is particularly useful in the diagnosis and study of viral disease. These techniques are not as sensitive as PCR (polymerase chain reaction), in which small amounts of target DNA in biologic material are amplified and identified. Small amounts of target DNA of microbes (for example) can be identified in tissues, and RNA sequences can be identified after conversion to DNA and subsequent amplification.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The typical light microscope can magnify to about 1000 $\times$  and is adequate for routine histopathology. Specialized microscopes such as dark field, phase contrast, and fluorescence microscopes are also used, often for identification of microbes. In both diagnostic and experimental settings, electron microscopy is used to visualize the subcellular structure of cells and microbes. Transmission electron microscopy of ultrathin sections allows resolution of ultrafine structures of less than a nanometer. Scanning electron microscopy allows the ultrafine observation of surfaces. Specialized analytical electron microscopes are also in use. Finally, laser capture microdissection allows pathologists to isolate and capture groups of similar cells from tumors or a diseased tissue. Using DNA microarrays, the genes expressed by these cells can be identified and characterized, thus providing a “genetic fingerprint” of the disease process that clinically can be used to develop therapeutic strategies and assess the outcome.

### 1.5 THE NORMAL CELL

#### 1.5.1 COMPONENTS OF NORMAL CELLS AND THEIR VULNERABILITIES

The early pathologists Morgagni and Bichat emphasized the importance of organs and tissues as the seat of disease. Virchow later focused on individual cells as the primary cause of abnormal function and structure associated with diseases. Before we can interpret lesions of sick cells, it is essential that we understand normal cell structure and function. The cell can be visualized simplistically as a membrane-enclosed compartment, subdivided into numerous smaller compartments (organelles) by membranes (Fig. 1-1). This vast interconnecting system of membrane-bound spaces is termed the “cytostatic network.” The function of these organelles is largely determined by the type and quantity of specific enzymes associated with each membrane and in the cytoplasmic matrix.

It is essential to have a clear understanding of the structure and function of the components of normal cells and how they are interrelated in a normally functioning cell. Cell membranes and organelles serve as targets for injury by microbes, harmful environmental agents, and a variety of genetic, metabolic, and toxicologic diseases discussed in greater detail in the Pathology of Organ Systems chapters of this book.

##### 1.5.1.1 CELL MEMBRANES

Cell membranes are a fluid phospholipid bilayer penetrated by numerous specific proteins (Fig. 1-2). The two main biologic functions of these membranes are (1) to serve as selective barriers and (2) to form a structural base for the enzymes and receptors that determine cell function. Cell membranes form the boundaries of many organelles and separate them from the cytosol.

5

7

## Pathologic Basis of Veterinary Disease, 4th Edition

Fig. 1-1 Cell structure and the organization of organelles, cytoskeleton, and membrane enhancements. (From McCance K, Huether S: Pathophysiology: the biologic basis for disease in adults and children, ed 4, St Louis, 2002, Mosby.)

Fig. 1-2 **Fluid mosaic model of cell membrane structure.** The lipid bilayer provides the basic structure and serves as a relatively impermeable barrier to most water-soluble molecules. (From Thibodeau GA, Patton KT: Structure & function of the human body, ed 11, St Louis, 2000, Mosby.)

**Fig. 1-3 Functions of transmembrane proteins.** A variety of functions are performed by different types of cell membranes as shown. (From Raven PH, Johnson GB: Understanding biology, ed 3, Dubuque, Iowa, 1995, Brown.)

The plasma membrane is the cell's first contact with injurious agents. Microvilli and cilia are specialized areas of the plasma membrane and are often specifically altered in disease (Fig. 1-1). Plasma membranes separate the interior of the cell from external surfaces, neighboring cells, or surrounding matrix. Surface proteins, such as fibronectin, play a role in cell to cell and cell to extracellular matrix interactions. Transmembrane proteins embedded in the phospholipid bilayer serve in variety of structural, transport, and enzymatic functions essential to cell viability (Fig. 1-3). It is these transmembrane proteins that are often used by infectious microbes to enter or use cell systems during their life cycles, thus initiating a process that often results in injury to the host cell.

### 1.5.1.2

#### CYTOSOL

The cytosol is the watery gel in which the cell's organelles and inclusions are dispersed. Many chemical reactions occur in the cytosol mediated by "free" enzymes. The cytosol is a highly organized microtrabecular network.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1.5.1.3

### MITOCHONDRIA

Mitochondria (singular = mitochondrion) are the “powerhouses” of highly specialized eukaryotic cells. They are the site of fatty acid oxidation, the citric acid cycle, and oxidative phosphorylation. Transfer of electrons from reduced cytochrome oxidase to molecular oxygen is the final and critical step culminating in these catabolic pathways. Important structural components of a mitochondrion are the outer membrane, outer compartment, inner membrane, inner compartment (matrix), cristae, and mitochondrial DNA. Damage to mitochondria results in diminished adenosine triphosphate (ATP) production and if damage is unchecked, cell death (Fig. 1-6).

7

1.5.1.4

### NUCLEUS

The nucleus is that portion of the cell responsible for storage and transmission of genetic information (Fig. 1-1). Chains of DNA, complexed to protein, are chromatin. Areas of uncoiled chromatin (euchromatin) are active in the generation of mRNA for protein synthesis. Highly coiled chromatin (heterochromatin) is inactive in transcription. The outer nuclear membrane is continuous with that of the rough endoplasmic reticulum (RER).

8

1.5.1.5

### NUCLEOLUS

The nucleolus is a basic organelle of the nucleus and is composed of RNA, nucleolus-associated chromatin, and protein (Fig. 1-1). It functions in the synthesis of rRNA, essential in protein synthesis. The nucleolus can be basophilic or eosinophilic, and its prominence is a subjective measure of the cell's synthetic activity.

1.5.1.6

### ROUGH ENDOPLASMIC RETICULUM

The RER is a network of intracellular membranes studded with ribosomes (Fig. 1-4). RER is prominent in cells producing large amounts of extracellular protein (e.g., reactive fibroblasts, hepatocytes, plasma cells, and pancreatic acinar cells). The RER is responsible for the basophilia of the cytoplasm because of the numerous ribosomes, which contain acid (i.e., RNA).

Fig. 1-4 **Membrane systems.** The rough endoplasmic reticulum and Golgi apparatus are important organelles in cellular biosynthesis of proteins and glycoproteins inserted into cell membranes and used in and secreted from cells. Transcription, translation, assembly, modification, and packaging of these molecules occur in an orderly sequence from the nucleus to the cell membrane as shown. Alterations in one or more of these steps can result in cell injury and serve as the underlying pathogenesis of a disease process. (From Copstead L, Banasik J: Pathophysiology, ed 3, St Louis, 2005, Mosby.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 1.5.1.7 SMOOTH ENDOPLASMIC RETICULUM

Smooth endoplasmic reticulum (SER) is a tubular or vesicular form of cell membrane that lacks ribosomes (Fig. 1-1). SER is the locus of enzymes that metabolize steroids, drugs, lipids, and glycogen. It gives the cytoplasm a pale, finely vacuolated appearance as viewed in the light microscope.

### 1.5.1.8 GOLGI COMPLEX

The Golgi complex consists of several lamellar stacks or flattened sacs of membranes, vesicles, and vacuoles (Fig. 1-4). It functions in the synthesis of complex proteins by the addition of carbohydrate molecules and in the production of secretory vesicles and lysosomes.

### 1.5.1.9 LYSOSOMES

Lysosomes are small membrane-bound vesicles laden with hydrolytic enzymes essential for intracellular digestion (Fig. 1-1). They are discussed more completely as components of phagocytic cells. Peroxisomes are similar to lysosomes but also play a role in energy metabolism.

### 1.5.1.10 MICROFILAMENTS, INTERMEDIATE FILAMENTS, AND MICROTUBULES

These structures are composed of protein subunits and function in the cytoskeleton and in cell movement (Fig. 1-5). They have a prominent role in the mitotic spindle, cilia, microvilli, neurons, myocytes, and phagocytic cells. Many cell types besides muscles, for example, contain actin microfilaments.

Intermediate filaments are about 10 nm in diameter and are important in cell shape and movement. Different cell types have different intermediate filaments; for example, cytokeratins are found in epithelial cells, desmin in muscle cells, and vimentin in cells of mesenchymal origin such as fibroblasts. Intermediate filaments can be useful markers for classifying undifferentiated neoplasms.

### 1.5.1.11 CELLULAR INCLUSIONS

Inclusions include glycogen granules, proteinaceous vacuoles, lipid debris, hemosiderin, viral particles, and calcium granules (discussed in greater detail later in this chapter). Some of these are normal, whereas others are the result of cell injury and will be discussed later in this chapter in the section dealing with intracellular and extracellular accumulations.

### 1.5.1.12 EXTRACELLULAR MATRIX

Although not part of the cell itself, the ECM and its integrity influences cell health and function (see Chapter 4 and Fig. 4-19). ECM includes basement membranes and interstitial matrices composed of various collagens, proteoglycans, and adhesive glycoproteins among a variety of other molecules that interact with cells by means of various integrin molecules. Basement membrane integrity, for example, is essential for the proper structure and functioning of epithelial cells. Other components of the ECM influence how cells grow and differentiate.

8

9

Fig. 1-5 **Cytoskeleton.** The complexity of and interrelations between intermediate filaments, microtubules, endoplasmic reticulum, and other cytoplasmic organelles that can be involved in the pathogenesis of diseases are shown. (From McCance KL, Huether SE: Pathophysiology: the biologic basis for disease in adults and children, ed 4, St Louis, 2002, Mosby.)

### 1.6 CAUSES OF CELL INJURY

Causes of cell injury are numerous and can be classified in a variety of ways. Some causes, such as physical trauma, viruses, and toxins, are clearly extrinsic, whereas others, such as spontaneous genetic mutations, are clearly intrinsic. Others, such as workload imbalance, nutritional abnormalities, and immunologic dysfunctions, can have components of both extrinsic and intrinsic mechanisms. General mechanisms of injury include ATP depletions (often caused by hypoxia), membrane damage (a result of a myriad of causes, including oxygen-derived free radicals), disturbances of cellular metabolism, and genetic damage (Fig. 1-6).

Understanding disease starts with understanding the cell. Until the nineteenth century, the dominant theory of disease in western societies was humoral pathology wherein disease was attributed to a maldistribution of body fluids or “humors.” In the mid 1800s, Rudolph Virchow, a German pathologist now considered to be the founder of modern pathology, redefined pathology and medical science by his idea of the body as an organization of cells, each suited for specific functions. He taught that disease resulted from injury to, or dysfunction of, specific

## Pathologic Basis of Veterinary Disease, 4th Edition

populations of cells. The recent rapid advancement in medical science is owed to a great extent to Virchow's original emphasis on cellular pathology and more recently on molecular pathology.

Cells can be injured by a large number of causes (etiologic agents). Fortunately the types of responses of the cell to injury are not as large. The responses to injury depend on many factors, including the type of agent, the extent of injury, the duration of injury, and the cell type affected. Renal tubular cells deprived of adequate blood supply, for example, may exhibit only cell swelling, if oxygen is soon restored. Prolonged lack of adequate blood supply (ischemia) can lead to cell death. Diminished but sublethal reduction in blood supply may result in cells adapting by decreasing their metabolic rates, which could lead to recovery or, if adaptation is inadequate, then eventually death.

Cells respond to stimuli and stressors in a variety of ways to maintain homeostasis. Cell injury takes place when a cell can no longer maintain a steady state. Some types of cell injury, such as cell swelling, can be reversible if the extent and duration of injury is not excessive. But if the injury exceeds certain limits, cell death and irreversible change occur. Not all cell injury results in cell death. Cell injury may be sublethal and result in a variety of types of cell degenerations or accumulations and/or adaptations by the cell to the injury. In essence, cells or tissues respond to injury (or stress) in three important ways: (1) adaptation, (2) degeneration or intracellular or extracellular accumulations, and (3) death (Fig. 1-7).

9  
10

**Fig. 1-6 Cellular and biochemical sites of damage in cell injury.** ATP, Adenosine triphosphate. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

**Fig. 1-7 Stages in the cellular response to stress and injurious stimuli.** (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Pathologically, reversible cell injury is injury from which the cell can adapt or recover and thus return to normal or nearly normal function. Irreversible cell injury results in a dead cell. This distinction seems clear cut, but the point at which a cell transitions from reversible cell injury to irreversible cell injury (i.e., "the point of no return") has

## Pathologic Basis of Veterinary Disease, 4th Edition

---

been a major research challenge for the past few decades and remains so today (Fig. 1-8). The lesions of reversible and irreversible cell injury will be discussed in greater detail in subsequent sections; however, in summary, the cytomorphologic changes characteristic of irreversible cell injury include the following:

- Plasma membrane damage
- Calcium entry into the cell
- Mitochondrial swelling and vacuolization
- Amorphous densities (likely calcium) in the mitochondria
- Lysosomal swelling

The causes of reversible and irreversible cell injury resulting in cell death, cell adaptation and degeneration, and finally cellular accumulations will be now be discussed.

### 1.6.1 OXYGEN DEFICIENCY

Hypoxia is one of the most common and important causes of cell injury and death (Fig. 1-8). Hypoxia is a partial reduction in the O<sub>2</sub> concentration supplied to cells or tissue; a complete reduction is referred to as anoxia.

Oxygen is critically important for oxidative phosphorylation, especially in highly specialized cells such as neurons, hepatocytes, cardiac myocytes, and renal tubule cells. Hypoxia can result from inadequate oxygenation of blood as a result of heart failure or respiratory failure, loss or reduction of blood supply (ischemia), reduced transport of O<sub>2</sub> in blood (e.g., anemia or carbon monoxide toxicity), and blockage of cell respiratory enzymes (cyanide toxicosis).

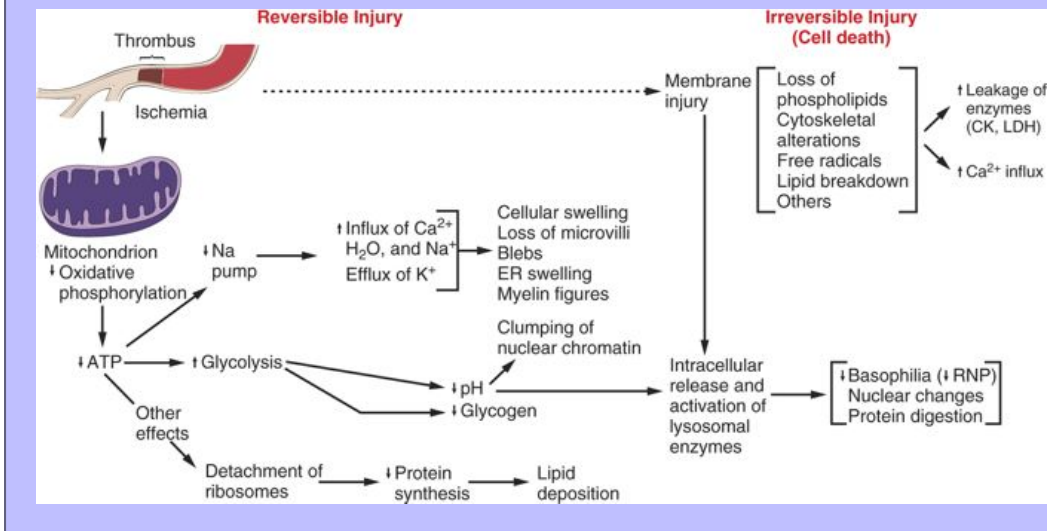

### 1.6.2 PHYSICAL AGENTS

Trauma, extremes of heat and cold, radiation, and electrical energy may seriously injure cells. Trauma may cause direct rupture and death of large numbers of cells, or it may damage the blood supply to cells. Extreme cold impairs the blood flow, and intracellular ice crystals rupture cell membranes. Extreme heat denatures essential cell enzymes and other proteins. Excessive heat can increase the rate of metabolic reactions so that substrates, water, and pH changes reach lethal levels. Electricity generates great heat as it passes through tissue. It also alters conduction of nerves and muscle. Ionizing radiation causes ionization of cellular water with production of highly reactive “free radicals” that injure cell components. Many forms of radiation may damage genetic material resulting in reproductive death of cells, genetic defects, and neoplasia.

10

11

**Fig. 1-8 Postulated sequence of events in reversible and irreversible ischemic cell injury.** Note that although reduced oxidative phosphorylation and adenosine triphosphate (ATP) levels have a central role, ischemia can cause direct membrane damage. ER, Endoplasmic reticulum; CK, creatine kinase; LDH, lactate dehydrogenase; RNP, ribonucleoprotein. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 1.6.3 INFECTIOUS AGENTS

Viruses are obligate intracellular parasites that redirect host cell enzyme systems toward synthesis of viral proteins and genetic materials, to the detriment of host cells. Cell changes induced by viral agents vary from little effect to cell death or neoplastic transformation.

Injury due to bacterial infection varies and can result from the action of potent toxins on specific host cells (clostridial infections, enterotoxigenic *Escherichia coli* infection) or from an overwhelming or ineffective inflammatory response to uncontrolled bacterial replication in tissue. Some bacteria, such as *Lawsonia intracellularis*, can result in excessive intestinal epithelial cell replication.

Mycotic agents resist destruction by the body that can lead to progressive, chronic inflammatory disease with loss of normal host tissues. Protozoal agents replicate in specific host cells, often resulting in destruction of infected cells. Metazoan parasites cause inflammation, distort tissue, and use host nutrients.

### 1.6.4 NUTRITIONAL DEFICIENCIES AND IMBALANCES

Dietary protein-calorie deficiencies are seen sporadically in animals and humans (known as kwashiorkor). These deficiencies require metabolic adaptation by large populations of cells. Lipolysis, catabolism of muscle protein, and glycogenolysis enable short-term survival. Calorie excess, as seen in many pets and people of affluent

## Pathologic Basis of Veterinary Disease, 4th Edition

---

societies, is implicated in cardiovascular disease and several other diseases. Vitamin and mineral imbalances are common due to errors in formulating rations and hypersupplementation by well-meaning animal owners.

### 1.6.5 GENETIC DERANGEMENT

A normal genetic apparatus is essential for cell homeostasis. Mutations, whatever their origin, may cause no disease, may deprive a cell of a protein (enzyme) critical for normal function, or may be incompatible with cell survival. A few examples of genetic diseases are defects of clotting factors (hemophilia), lysosomal storage disease (mannosidosis), combined immunodeficiency of Arabian foals, and defects of collagen synthesis (dermatosparaxis). Besides causing overt disease, some genotypes cause the host to be more prone to certain types of extrinsic or intrinsic disease, a condition often termed genetic predisposition.

### 1.6.6 WORKLOAD IMBALANCE

Cells that are overworked may adapt to the demand or eventually become exhausted and die. Conversely, cells that are no longer stimulated to work may shrink in size and waste away. An example is the way endocrine tissues react to the presence or absence of specific trophic hormones. Muscle fibers, deprived of work or their nerve supply, will atrophy and ultimately disappear, leaving a fibrous stroma.

11

12

### 1.6.7 CHEMICALS, DRUGS, AND TOXINS

Chemicals, drugs, and toxins influence cells by a multitude of mechanisms. Drugs produce their therapeutic effects by modifying the function (and morphology) of specific populations of cells. Most drugs cause these cells to adapt within a tolerable range of homeostasis. Chemicals, including drugs and toxins, can block or stimulate cell membrane receptors, alter specific enzyme systems, produce toxic free radicals, alter cell permeability, damage chromosomes, modify metabolic pathways, and damage structural components of cells.

### 1.6.8 IMMUNOLOGIC DYSFUNCTION

The immune system may fail to respond to infectious agents and other antigens as a result of congenital or acquired defects of lymphoid tissue or their products. Examples of congenital defects are thymic aplasia of nude mice and combined immunodeficiency of Arabian foals. Affected animals may die at an early age from infection by opportunistic microorganisms. Acquired immunodeficiency disease may be transient and results from damage to lymphoid tissue by viral infection, chemicals, and drugs.

The immune response directed toward foreign antigens (pathogenic organisms) is usually beneficial to the host, but sometimes the response is misdirected against antigens of host cells. This large group of diseases is referred to as autoimmune disease. An inappropriate or exaggerated response to certain antigens results in immunologic disease referred to as hypersensitivity (allergy). Some examples are anaphylaxis, feline asthma, and flea allergy dermatitis. The activity of the immune system is greatly amplified by its effect on serum complement and inflammation. These reactions often lead to serious injury to the kidney, skin, and joints.

### 1.6.9 AGING

The diminished capacity of aged cells and tissue to carry out their normal functions can hardly be disputed. One can argue that aging is simply the culmination of life's injuries inflicted by chemicals, infectious agents, work imbalances, or poor nutrition. We use the aging category for those lesions commonly found in aged animals;

## Pathologic Basis of Veterinary Disease, 4th Edition

---

lesions for which we have no other defensible mechanistic explanation. Some of the lesions commonly found in older animals include: nodular hyperplasia of parenchymal cells in the liver, pancreas, adrenal, spleen, and thyroid. There appear to be defects in growth control of these cell populations, but the cause is unclear. Aged cells may suffer a lifetime of damage to their DNA, or there may be accumulation of cellular debris that interferes with normal cell functions. One could argue that many cancers are caused by old age, rather than by exposure to specific chemicals, foods, viruses, or other insults.

### 1.7 REVERSIBLE CELL INJURY

#### 1.7.1 ACUTE CELL SWELLING

Cell swelling, also called hydropic degeneration, is the most common and fundamental expression of cell injury (Fig. 1-9). It is manifested as increased cell size and volume resulting from an overload of water caused by a failure of the cell to maintain normal homeostasis and regulate the ingress and excretion of water. It is accompanied by modification and degeneration of organelles. Mechanisms responsible for acute cell swelling usually involve damage to cellular membranes, failure of cellular energy production, or injury to enzymes regulating ion channels of membranes. Cell swelling occurs in response to loss of the cell's homeostasis secondary to mechanical, hypoxic, toxic, free radical, viral, bacterial, and immune-mediated injuries.

The functional and morphologic changes begin with increased uptake of water and then to diffuse disintegration of organelles and cytoplasmic proteins. Cell swelling must be distinguished from cell enlargement (hypertrophy) that is caused by an increase of normal organelles. Organs composed of swollen cells are themselves swollen. Affected organs are larger and heavier than normal and pale in color. The parenchyma of swollen organs such as kidney and liver may bulge a little from beneath their capsule when incised. Because of the increase of intracellular water, the specific gravity of affected tissues is slightly less than those of normal tissues.

##### 1.7.1.1 NORMAL CELL VOLUME CONTROL AND MECHANISMS OF ACUTE CELL SWELLING

In the normal cell, energy derived from ATP drives the  $\text{Na}^+ - \text{K}^+$  ion pumps within cell membranes to continuously drive  $\text{Na}^+$  out of the cell in exchange for  $\text{K}^+$  moving into the cell. For each molecule of ATP used, the pump moves three  $\text{Na}^+$  out of the cell and two  $\text{K}^+$  into the cell. By this means the ion pumps maintain the transmembrane ionic gradients required for normal nerve and muscle function. Because water moves passively across cell membranes in response to the osmotic pressure gradient generated by  $\text{Na}^+$  and proteins, the  $\text{Na}^+ - \text{K}^+$  pump is the key to regulation of intracellular water. The best studied laboratory models of cell swelling are: (1) hypoxia induced failure of ATP synthesis and (2) carbon tetrachloride ( $\text{CCl}_4$ )–induced membrane damage.

12

13

**Fig. 1-9 The process of acute cell swelling (hydropic degeneration).** ATP, Adenosine triphosphate. (From Huether S, McCance K: Understanding pathophysiology, ed 3, St Louis, 2004, Mosby.)

### 1.7.1.2 HYPOXIC INJURY RESULTING IN ACUTE CELL SWELLING

Hypoxia is probably the most important fundamental cause of acute cell swelling. Hypoxia-induced cell injury results from any defect in the transport of  $O_2$ , from inspired air to its role as the final acceptor of electrons from cytochrome oxidase in oxidative phosphorylation. Ischemia is reduced blood flow to a region of the body, usually because of obstruction of the blood supply. Blockage of coronary arteries by atherosclerotic plaque leads to ischemia and hypoxic injury to heart muscle, a common cause of “heart attacks” in humans. Therefore cellular hypoxia occurs with suffocation, anemia, pneumonia, shock or other damage to the circulation, and interference with mitochondrial enzymes.

In acute hypoxic injury, cell  $O_2$  is depleted in moments, aerobic oxidative phosphorylation stops, and ATP levels fall. The drop in cellular ATP stimulates phosphofructokinase, the initial regulator step of anaerobic glycolysis. The metabolic switch to anaerobic metabolism of glucose rapidly depletes the cell's glycogen stores and leads to the accumulation of intracellular lactate and inorganic phosphates. Although the anaerobic generation of ATP is inefficient, it provides for some short-term survival. Some highly specialized cell types such as neurons cannot generate ATP anaerobically and thus are especially prone to hypoxic injury.

Ultimately this deficiency of ATP leads to a failure of  $Na^+K^+$  pumps and loss of cell volume control.

The cardiac glycosides of plant origin, digitalis and ouabain, specifically inhibit the action of the  $Na^+K^+$  pump. This inhibition modifies the contractility of cardiac myocytes but it may also cause them to swell.

1.7.1.3

### CELL MEMBRANE INJURY IN ACUTE CELL SWELLING

Damage to the cell membranes, both plasma membranes and organelle membranes, destroys the selective permeability barrier that retains proteins and electrolytes within the cytosol and that restricts the entry of  $\text{Na}^+$ ,  $\text{Ca}^{++}$ , and water from the extracellular space. Failure of the barrier results from chemical modification of phospholipids by free radicals, covalent binding of toxic chemicals to macromolecules, interference with ion channels, and insertion of transmembrane protein complexes (e.g., complement activation).

The hepatotoxicities of  $\text{CCl}_4$  and chloroform provide classic examples of cell membrane injury ([Fig. 1-10](#)).

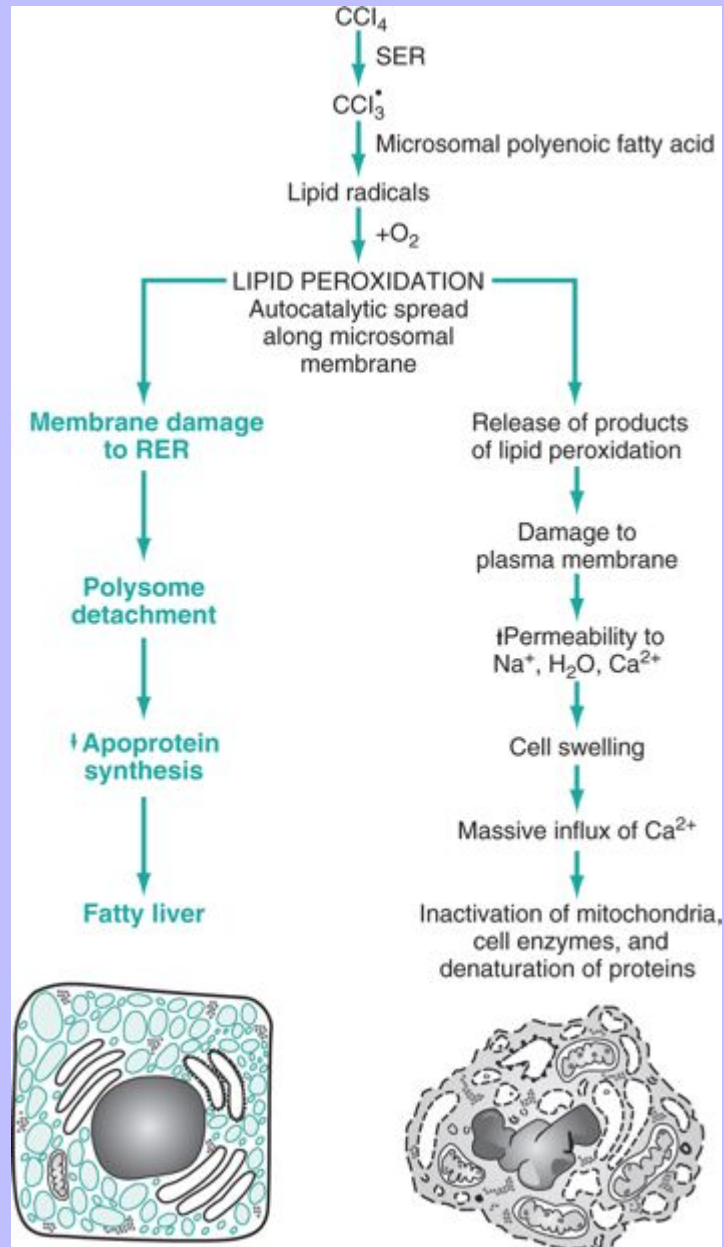

13

Toxic effects of  $\text{CCl}_4$  occur when the chemical is converted to the trichloromethyl radical  $\text{CCl}_3$  by the mixed-function oxidase system of the SER in hepatocytes. The toxic metabolite,  $\text{CCl}_3$ , next causes progressive lipid peroxidation of unsaturated fatty acids of cellular membranes, progressing from the SER to mitochondria and other cell membranes. Chloroform is toxic to hepatocytes when it is metabolized to the electrophilic metabolite, phosgene ( $\text{CCl}_2\text{O}$ ). The hepatic lesions associated with these two toxins are indistinguishable, and both may result in fatty liver.

14

Fig. 1-10 **Sequence of events leading to fatty change and cell necrosis in carbon tetrachloride ( $\text{CCl}_4$ ) toxicity.** *RER*, Rough endoplasmic reticulum; *SER*, smooth endoplasmic reticulum. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Besides toxins, other processes may cause cell membrane injury leading to acute cell swelling. The membrane-attack complex of serum complement (see [Chapter 3](#)) and the hemolysin of streptococci (streptolysin-O) penetrate cell membranes to form a channel for free passage of water, proteins, and electrolytes between intracellular and extracellular compartments. Affected cells are quickly lysed by water overload (hypotonic lysis). Cytotoxic effects of NK (natural killer) cells are mediated in part by the implantation of similar hollow protein-complexes into target cell membranes.

The sequence of events in acute cell swelling caused by hypoxia or ischemia is as follows:

1. Hypoxia—deficiency of  $O_2$
2. Decrease of oxidative phosphorylation and ATP
3. Increased glycolysis, increased intracellular lactate, and depletion of glycogen stores
4. Failure of  $Na^+ - K^+$  pump due to ATP deficiency
5. Net influx of  $Na^+$ ,  $Ca^{++}$ , and  $H_2O$  with loss of intracellular  $K^+$  and  $Mg^{++}$
6. Swelling of mitochondria and the cytoplasmic network (RER, SER, Golgi, and outer nuclear membrane)
7. Detachment of ribosomes, clumping of nuclear chromatin, loss of microvilli, vesiculation of endoplasmic reticulum (ER), formation of membrane whorls (“myelin figures”)
8. Severe disruption of cell membranes, influx of  $Ca^{++}$  into mitochondria and cytosol, overall cell enlargement, and clearing of the cytosol
9. Irreversible cell injury, cell death (necrosis)

When acute cell swelling results from membrane injury, the sequence of events is similar to those listed previously, except that changes start at about step 5 or 6.

### 1.7.1.4 MORPHOLOGY OF ACUTE CELL SWELLING

#### 1.7.1.4.1 Gross Appearance

Acute cell swelling is recognized as pallor, organ swelling, and decreased specific gravity. For example, the liver will be pale and somewhat turgid ([Fig. 1-11, A](#)). The parenchyma of organs with capsules may bulge, when incised.

#### 1.7.1.4.2 Microscopic Appearance

The influx of water dilutes the cytoplasmic matrix and dilates organelles to give cells a pale, finely vacuolated appearance (cloudy swelling). Renal tubule epithelial cells bulge and impinge on the tubular lumen. Swollen hepatocytes and endothelial cells intrude upon and diminish vascular lumens. Although

## Pathologic Basis of Veterinary Disease, 4th Edition

mechanisms of cell swelling are limited, variations in appearance may occur because of differences in cell type and cause of injury.

Hydropic degeneration (vacuolar degeneration) is a common term used for the microscopic appearance of acute cell swelling (Fig. 1-11, *B*). It occurs in endothelium, epithelium, alveolar pneumocytes, hepatocytes, renal tubular epithelial cells, and neurons and glial cells of the brain. Cytoplasm of affected cells contains translucent vacuoles that fail to stain for fat or glycogen (two other causes of vacuolar degeneration). These vacuoles represent swollen mitochondria and dilated cisternae of the Golgi and ER. Ballooning degeneration is an extreme variant of hydropic degeneration in which cells are greatly enlarged and the cytoplasm is basically a clear space (Fig. 1-12). Ballooning degeneration is typically seen in epidermal cells infected by epitheliotropic viruses (e.g., pox virus). This lesion frequently progresses to the formation of vesicles or bullae (blisters) from lysis of the epidermal cells. These viral infections cause both degradation of cytoplasmic proteins (cytoplasmic proteolysis) and net flux of water into the cytoplasm.

14

15

**Fig. 1-11 Acute cell swelling, liver, mouse.** **A**, Hepatic swelling in a mouse exposed to chloroform 24 hours previously. The accentuated lobular pattern and slight pallor in the liver on the left are the result of acute cell swelling (hydropic degeneration) and necrosis of centrilobular hepatocytes. The right liver is normal. **B**, Liver from a mouse with chloroform toxicosis. While many hepatocytes in the centrilobular areas (*at right*) are necrotic, several cells at the interface of normal and necrotic (*arrows*) are still undergoing acute cell swelling (hydropic degeneration). H&E stain. (*A and B*, Courtesy Dr. L.H. Arp.)

## Pathologic Basis of Veterinary Disease, 4th Edition

1.7.1.4.3

### Ultrastructural Appearance

As visualized with the electron microscope, swollen cells have lost and distorted cilia, microvilli, and attachment sites as well as “blebbing” of cytoplasm at the cell surfaces. The cytoplasm is rarefied, and the cisternae of the ER, Golgi, and mitochondria are dilated. The cytocavitary network becomes fragmented into numerous vesicles. Proteins and  $\text{Ca}^{++}$  precipitate in the cytoplasm and in organelles.

**Fig. 1-12 Ballooning degeneration, papular stomatitis, oral mucosa, cow.** Cells infected by some types of virus, such as papular stomatitis virus, are unable to regulate their volume and swell at certain stages of the infection. These cells may become very large (ballooning degeneration) and eventually rupture. Some of the cells have viral inclusion bodies (*arrows*). H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

1.7.1.5

### SIGNIFICANCE AND FATE OF ACUTE CELL SWELLING

Injured cells that can no longer regulate water and electrolytes are no better equipped to maintain other cell functions. Significance to the patient depends on the number of cells affected and the immediate importance of the lost cell function. Cells highly vulnerable to hypoxia and cell swelling include cardiac myocytes, proximal renal tubule epithelium, hepatocytes, and endothelium. In the central nervous system (CNS), besides endothelium, also neurons, oligodendrocytes, and astrocytes are swollen, and the process in the CNS is called cytotoxic edema (see [Chapter 14](#)). Swollen neurons fail to conduct nervous impulses, resulting in stupor or coma. Swollen myocardial cells contract with less force or with an abnormal rhythm. Swollen renal epithelium may not only fail to absorb and secrete but may also compress delicate interstitial blood vessels, resulting in further injury. Capillaries lined by swollen endothelium are prone to obstruction, exacerbating the

## Pathologic Basis of Veterinary Disease, 4th Edition

lesions by worsening cellular hypoxia. Injured cells with abnormal membrane permeability may be detected by finding their specific cytoplasmic enzymes in serum.

15

If adequate oxygen is restored to the cells and membrane injury is repaired before a certain point is reached, the “point of no return,” most cells can be restored to normal or nearly normal function. What happens when the stage of reversibility is passed is the topic of the subsequent sections beginning with cell death.

16

In summary, cell swelling is a manifestation of reversible, sublethal cell injury. However, unless the cause of injury to critically important cell types is removed quickly, progressive injury to these dependent cells and tissues may culminate in the death of the animal.

**Fig. 1-13 Normal cell and the changes in reversible and irreversible cell injury.** Reversible injury is characterized by generalized swelling of the cell and its organelles, blebbing of the plasma membrane, detachment of ribosomes from the endoplasmic reticulum, and clumping of nuclear chromatin. Transition to irreversible injury is characterized by increasing swelling of the cell, swelling and disruption of lysosomes, presence of large amorphous densities in swollen mitochondria, disruption of cellular membranes, and profound nuclear changes. The latter include nuclear condensation (pyknosis), followed by fragmentation (karyorrhexis) and dissolution of the nucleus (karyolysis). Laminated structures (myelin figures) derived from damaged membranes of organelles and the plasma membrane first appear during the reversible stage and become more pronounced in irreversibly damaged cells. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 1.8 IRREVERSIBLE CELL INJURY AND CELL DEATH

As we have just seen, major mechanisms of acute cell swelling are hypoxia, including ischemia, and membrane injury, often by toxins. Cell swelling can be reversible if the extent and duration of injury is not excessive. But if the injury exceeds certain limits (discussed shortly), cell death occurs (Fig. 1-13). Not all cell injury results in cell death. Cell injury may be sublethal and result in a variety of types of cell degenerations and/or adaptations by the cell to the injury. In essence, cells or tissues respond to injury (or stress) in three important ways: (1) adaptation (with or without accumulations or degenerative changes), (2) reversible injury (again with or without subcellular changes) and (3) death. In this section we will deal with cell death. Various types of cell adaptations, degenerations, and accumulations will be addressed in subsequent sections.

16

17

#### 1.8.1 CELL DEATH

Cell death can occur in many ways. For example, extremes of temperature or direct trauma may result in nearly instantaneous destruction or death of cells. On the other hand, death of an animal (somatic death) results in eventual death of all cells that make up the animal (postmortem autolysis). During most of the last century, cell death and necrosis were thought of as being more or less the same and in most pathologic situations, necrosis was usually thought to be preceded by cell swelling as discussed earlier. It is clear that cells die before macroscopic or histologic evidence can be detected. Although necrosis can be defined as the death of cells in a living animal, it should be understood to mean the specific morphologic changes (either macroscopic or microscopic) indicative of cell death in a living animal.

**Fig. 1-14 The sequential ultrastructural changes seen in necrosis (left) and apoptosis (right).** In apoptosis, the initial changes consist of nuclear chromatin condensation and fragmentation, followed by cytoplasmic budding and phagocytosis of the extruded apoptotic bodies. Signs of cytoplasmic blebs, and digestion and leakage of cellular components characterize necrosis. (Adapted from Walker NI, Harmon BV, Gobe GC, Kerr JF: *Methods Achiev Exp Pathol* 13:18-54, 1988.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In the last few decades of the twentieth century it became clear that cells die also by shrinkage, both under physiologic and pathologic circumstances, and this complex and now well-studied process has become known as apoptosis. Cell death then began to be classified in two major types: necrosis or apoptosis. Because of the long history of use of necrosis and because apoptosis, cell death with shrinkage, is distinctly different from death following swelling, the term *oncosis* (onco-meaning swelling) has been proposed for what was previously termed necrosis. As in most biologic processes, it is not always possible to make the distinction between these two types of cell death based on histologic examination, and often both swelling and shrinkage are present.

How then are we to use the term *necrosis*? Attempts are being made by toxicologic pathologists to use the term *necrosis* for the histologic changes that occur following cell death by either mechanism, using oncotic cell death or apoptotic cell death when a distinction needs to be made. We will attempt to adhere to this distinction here, but long-used terminology does not easily change. The following sections first will discuss cell death following irreversible cell injury by hypoxia and cell membrane damage (oncotic necrosis), and then apoptosis or apoptotic necrosis (Fig. 1-14).

17

1.8.1.1

### ONCOSIS (ONCOTIC NECROSIS)

18

Oncosis is cell death following irreversible cell injury by hypoxia, ischemia, and membrane injury. Hypoxic injury, as discussed earlier in Acute Cell Swelling, is a common cause of cell death and oncotic necrosis. It is often due to blockage of or markedly diminished blood supply to an area (ischemia). Ischemic injury is typically more severe than hypoxia alone because not only is the amount of oxygen lowered in the tissue, but the inflow of metabolic substrates and nutrients are also decreased and cell waste and by-products accumulate, some of which are injurious in their own right. Cell membrane damage caused by toxins and other substances and mechanisms can also lead to necrosis, but the resulting morphologic changes are similar.

Acute cell swelling can result in necrosis or can be reversible. There has been much recent interest and research about those circumstances where injury is irreversible and necrosis results, and it is still not clear exactly where the point of no return is. Research has provided convincing evidence for the role of  $\text{Ca}^{++}$  in the eventual demise of severely injured cells. Earlier work consistently identified two features of irreversible cell injury: (1) an inability to restore mitochondrial function and (2) evidence of cellular membrane damage.

Research directed at understanding coronary heart disease has led to improved understanding. Heart muscle deprived of its blood supply (ischemia) suffers from hypoxia and substantial loss of cell volume regulation and the influx of  $\text{Ca}^{++}$  because of inadequate ATP to run the ion pumps. If the blood supply is resupplied to the ischemic area, often reversal of the injury is not attained, but instead injury is accelerated. It has been shown that restored blood flow results in a tremendous influx of calcium, and added membrane damage occurs shortly after the blood supply is reestablished. This phenomenon is now termed *reperfusion injury*. It has been found that pretreatment with the tranquilizer chlorpromazine prevents much of the  $\text{Ca}^{++}$  influx and irreversible cell injury. The reactivity of free  $\text{Ca}^{++}$  ion and its role as an intracellular messenger and enzyme activator are better known, and these actions are thought to cause the final demise of the cell in necrosis.

What does  $\text{Ca}^{++}$  do to cause the ultimate demise of many severely injured cells as it influxes from the extracellular space (Fig. 1-15)? At least one endogenous, membrane-bound phospholipase (phospholipase A) is activated by free  $\text{Ca}^{++}$ . Activated phospholipases then break down the normal phospholipids of the inner mitochondrial membrane and other cell membranes. These events then preclude any possibility for cell survival. Activation of phospholipases also generates arachidonic acid, the substrate for many lipid mediators

## Pathologic Basis of Veterinary Disease, 4th Edition

of inflammation (to be discussed later). Therefore it is usual to see some degree of inflammation around foci of necrosis. In addition to phospholipases,  $\text{Ca}^{++}$  also activates proteases that result in cytoskeleton and membrane damage, adenosinetriphosphatases (ATPases) that accelerate depletion of ATP, and endonucleases that result in chromatin degradation. Irreversible injury to mitochondrial membranes appears to be the death blow to the cell.

**Fig. 1-15 Sources and consequences of increased cytosolic calcium in cell injury.** ATP, Adenosine triphosphate. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

There is great interest in control of  $\text{Ca}^{++}$  influx into myocardial cells during and following myocardial infarction (heart attack). Drugs that act as  $\text{Ca}^{++}$  ion channel-blocking agents are being evaluated and used. Substances—such as antioxidants, including vitamin E—that decrease membrane damage caused by oxygen metabolites (free radicals) that are generated are also important. Decreasing the influx of inflammatory cells and impact of inflammatory mediators is also important in minimizing reperfusion injury.

1.8.1.2

### CELL MEMBRANE INJURY LEADING TO CELL DEATH

Chemical injury to cells in many cases may occur because of membrane damage. Classically studied and referred to in the section on acute cell injury is the toxicity for hepatocytes of  $\text{CCl}_4$  (Fig. 1-10). After ingestion and absorption by the gastrointestinal (GI) tract,  $\text{CCl}_4$  is transported via the portal vein to the liver where it enters hepatocytes.  $\text{CCl}_4$  itself is fairly innocuous, but metabolism by the cytochrome p450 system in the SER results in the formation of a toxic metabolite,  $\text{CCl}_3$ . This free radical causes lipid peroxidation of organelle membranes starting from the SER and spreading to other organelles and eventually to the limiting cell membrane. This outcome has a variety of consequences. Injury to mitochondria results in decreased oxidative metabolism, decreased ATP production, and consequently an influx of calcium into mitochondria. This outcome results in decreased activity of the sodium-potassium pump and dysregulation of cell volume and

18

19

## Pathologic Basis of Veterinary Disease, 4th Edition

massive intracellular increase in calcium with its lethal consequences. Direct damage to the plasma membrane itself by lipid peroxidation can have the same consequences to cell volume control and influx of calcium.

**Fig. 1-16 The role of reactive oxygen species in cell injury.**  $O_2$  is converted to superoxide ( $O_2^{\cdot -}$ ) by oxidative enzymes in the endoplasmic reticulum (ER), mitochondria, plasma membrane, peroxisomes, and cytosol.  $O_2^{\cdot -}$  is converted to  $H_2O_2$  by dismutation and thence to  $OH^{\cdot}$  by the  $Cu^{2+}/Fe^{2+}$ -catalyzed Fenton reaction.  $H_2O_2$  is also derived directly from oxidases in peroxisomes. Not shown is another potentially injurious radical, singlet oxygen. Resultant free radical damage to lipid (peroxidation), proteins, and DNA leads to various forms of cell injury. Note that superoxide catalyzes the reduction of  $Fe^{3+}$  to  $Fe^{2+}$ , thus enhancing  $OH^{\cdot}$  generation by the Fenton reaction. The major antioxidant enzymes are superoxide dismutase (SOD), catalase, and glutathione peroxidase. GSH, Reduced glutathione; GSSG, oxidized glutathione; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lysosomal swelling and release of hydrolytic enzymes can result in autodigestion of cell components. Injury to RER of the hepatocyte can result in decreased protein synthesis, and this deficiency then causes insufficient production of lipoproteins required to export lipids and then results in increased fatty acid content in the cell and hepatic lipidosis (see discussion later), if the changes are not lethal.

1.8.1.3

### FREE RADICAL INJURY

Injury to cell and organelle membranes can occur in many ways. One of the most common and important is free radical injury (Fig. 1-16). A free radical is any molecule that has an unpaired electron. These molecules are highly reactive, transient chemical species, generated as by-products of normal oxidative metabolism or by exposure to radiation, toxic gases, chemicals, and drugs. Most, but not all, are reactive oxygen radicals. Oxygen radicals are also produced by phagocytic cells in inflammatory lesions and account for significant damage to surrounding tissue. Antineoplastic drugs such as doxorubicin generate oxygen radicals that cause significant injury to cardiac myocytes. Cellular components at risk of free radical injury include proteins, membrane lipids, and nucleic acids. Lipid peroxidation of plasma membranes and organelle membranes by free radicals can have similar consequences to those described earlier from  $\text{CCl}_4$ .

19

20

Free radical injury is usually controlled by intracellular antioxidants such as superoxide dismutase (SOD), glutathione peroxidase, and vitamins E and C; however, injury can be catastrophic when these antioxidative systems are defective. In many species of domestic animals, severe cellular damage occurs to heart muscle when there is a deficiency of selenium or vitamin E in the tissues. Vitamin E is one of several cytoprotective molecules that acts as an antioxidant and inhibits production of or quenches free radicals, even in normal cell metabolism. Insufficient antioxidant activity can result in severe cell injury and necrosis as a consequence of the free radicals generated. Selenium is an essential component for some glutathione peroxidases, which also inactivate some free radicals generated within cells.

1.8.1.4

### MORPHOLOGIC APPEARANCE OF NECROTIC CELLS AND TISSUES (ONCOTIC NECROSIS)

In contrast to postmortem autolysis, necrosis occurs in the living animal, but the degradative processes of the cells involved are similar. One challenge to veterinarians and pathologists is to distinguish necrosis, tissues that died before somatic death, from tissues that died with the rest of the animal (postmortem autolysis).

At this point there may be some confusion about the term *autolysis*. Most veterinarians and pathologists use this term synonymously with postmortem changes. Technically, *autolysis* means the self-digestion or degradation of cells and tissues by the hydrolytic enzymes normally present in those tissues. Therefore by the strict definition, autolysis occurs in all tissue that die (and even before they die) regardless of whether cells die before or after the animal dies. Postmortem change includes both autolysis and putrefaction, which is the process by which bacteria break down tissues.

The appearance of necrotic cells varies with the tissue involved, the cause of cell death, and the duration of time. For our immediate purposes, *necrosis* here will for the most part be used to mean oncototic necrosis. Apoptotic necrosis will be discussed later.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1.8.1.4.1

### Ultrastructure of Necrotic Cells (Oncotic Necrosis)

Cells dying after acute cell swelling are obviously swollen. There is tremendous swelling of all mitochondria, ER is dilated and fragmented, chromatin is clumped, the nuclear membrane is folded, the cytoplasm is pale and structureless, and organelles are poorly visualized. As the intracellular and extracellular compartments reach equilibrium across the altered cell membrane, the cell collapses and shrinks like a hot air balloon that has lost its air. The cell is shrunken; cytoplasm and organelles are homogeneous, electron dense, and hard to identify. Specialized areas of the plasma membrane such as desmosomes, microvilli, and cilia are distorted or absent.

1.8.1.4.2

### Histologic Changes in Necrosis (Oncotic Necrosis)

Nuclear changes of dead cells are variable and are described by the terms pyknosis, karyorrhexis, and karyolysis (Fig. 1-17). All of the following nuclear changes may be visible in the same necrotic lesion. Basophilic fragments of nuclear debris can be confused with bacteria, protozoa, and calcium deposits. Histomorphology of the nucleus of a necrotic cell includes one or more of the following:

- Pyknosis. The nucleus is shrunken, dark, homogeneous, and round. Pyknosis may be a sequel to chromatin clumping of early degeneration.
- Karyorrhexis. The nuclear envelope is ruptured, and dark nuclear fragments are released into the cell cytoplasm.
- Karyolysis. The nucleus is extremely pale due to dissolution of chromatin presumably by action of RNAases and DNAases.
- Absence of nucleus. This is a later stage of karyolysis in which the nucleus has been completely dissolved or lysed.

Some cell lines have a preference for a type of nuclear change in necrosis. Necrotic lymphocytes often become pyknotic, sometimes karyorrhectic, followed by release of nuclear debris. Necrotic renal proximal tubular epithelial cells often have karyolytic nuclei, but the distal tubules may have predominantly pyknotic nuclei.

1.8.1.4.2.1

### Cytoplasmic changes in dead cells

Early in cell necrosis, the cytoplasm becomes homogeneous pink in H&E stained sections (Fig. 1-18). Increased eosinophilia may reflect a loss of ribosomal RNA, which is responsible for cytoplasmic basophilia, or a consolidation of cytoplasmic components as the cell collapses. Degradation of cytoplasmic proteins eventually gives the necrotic cell a pale, ghostlike appearance. Necrotic cells usually lose their adherence to basement membranes and neighboring cells so they are found free in tubules, alveoli, follicles, and other lumens or on surfaces. Rupture of cells with loss of cell integrity is the most obvious evidence of cell death.

20

22

**Fig. 1-17 Cytoarchitecture of cellular necrosis.** **A**, Schematic representation of nuclear and cytoplasmic changes in the stages of necrosis. **B**, Pyknosis and karyolysis, renal cortex, chloroform toxicosis, mouse. Some epithelial cells exhibit hydropic degeneration, whereas others are necrotic. Some necrotic cells exhibit pyknosis (*arrow*), whereas others have lost the nucleus or have a very pale nucleus (karyolysis) (*arrowhead*). H&E stain. **C**, Karyorrhexis, lymphocytes, spleen, dog. Spleen of a dog with parvovirus infection. Lymphocyte nuclei have fragmented because of the infection (*arrow*). H&E stain. Tyler, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. S. Newman, College of Veterinary Medicine, University of Tennessee.)

1.8.1.4.3

### Gross Appearance of Necrotic Tissue

Necrotic tissue is usually pale, soft and friable, and sharply demarcated from viable tissue by a zone of inflammation (Fig. 1-18). An exception to the pale color occurs when blood oozes into the necrotic tissue from damaged blood vessels in adjacent viable tissue as happens in renal infarcts which are often surrounded by a narrow (1 to 3 mm) red rim (active hyperemia). A sharp line of demarcation between necrotic and viable tissue is often a reliable means to distinguish necrosis from autolysis. It must be emphasized that necrotic changes are first apparent ultrastructurally (less than 6 hours), then histologically (6 to 12 hours), and finally grossly (24 to 48 hours). Therefore except for vascular changes, morphologic evidence of cell death is often sparse or absent in cases of peracute or acute death.

1.8.1.5

### TYPES OF ONCOTIC NECROSIS

Foci of necrosis in tissue have a limited number of morphologic appearances depending on the tissue involved, the cause of cell injury, and somewhat on the time since injury has occurred. Classification of necrotic lesions enables the pathologist to describe the lesion with a minimum of repetitious detail, but more than one type of necrosis may be seen in an organ or tissue. The following are classically or historically derived and although commonly used do not always accurately describe the complexity of what has happened to the involved cells and tissues.

1.8.1.5.1

### Coagulation Necrosis

Coagulation necrosis (coagulative necrosis) is characterized by preservation of the basic cell outlines of necrotic cells (Fig. 1-18). Cytoplasm is homogeneous and eosinophilic due to coagulation of cell proteins, similar to what happens to heat coagulation of proteins of a cooked egg white. Presumably the injury or subsequent cellular acidosis denatures not only structural proteins but also enzymes. This delays proteolysis of the cell. Nuclei are pyknotic, karyorrhectic, karyolytic, or absent. This form of necrosis may occur in any tissue except brain parenchyma, although it does occur initially in individual neurons. It is classically seen in kidney, liver, and muscle, and the necrotic tissue will eventually lyse within several days and be phagocytosed. Coagulation necrosis suggests hypoxic cell injury as seen in local loss of blood supply or in shock. Bacterial exotoxins and chemical toxins also cause the lesion. Infarction is necrosis due to ischemia. An infarct, for example, occurring in the human heart as a result of the blockage of a coronary artery by an atherosclerotic plaque is an area of coagulation necrosis due to a sudden loss of blood supply to an area.

1.8.1.5.2

### Caseation Necrosis

Caseation necrosis (caseous necrosis) implies conversion of dead cells into a granular friable mass grossly resembling cottage cheese (Fig. 1-19). The necrotic focus is composed of a coagulum of nuclear and cytoplasmic debris. Compared with coagulation necrosis, this is an older (chronic) lesion often associated with poorly degradable lipids of bacterial origin. Any tissue may be affected, and much of the necrotic debris is dead leukocytes. Dystrophic calcification commonly occurs later within the central parts of the lesion. The classic cause of this lesion is tuberculosis. Related bacteria, such as *Corynebacterium*, also cause this lesion in sheep. Delayed degradation of the bacterial cell wall is thought to play a role in the development of a lesion caused by these bacteria and results in a focus of caseous necrosis surrounded by granulomatous inflammatory cells and an outer fibrous connective tissue capsule.

22

23

**Fig. 1-19 Tuberculosis, lymph node, transverse section, ox.** **A,** The lymph has been replaced by a caseating granuloma. Note the caseous necrosis characterized by a pale yellow, crumbly exudate. **B,** Granulomatous inflammation in caseous necrosis. Cell walls are disrupted and tissue architecture is lost. Domingo, Autonomous University of Barcelona; and Noah's Arkive, College of Veterinary Medicine, University of Georgia. **B,** Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

1.8.1.5.3

### Liquefactive Necrosis

Liquefactive necrosis is the usual type of necrosis in the CNS, although the neuron cell bodies themselves initially show coagulation necrosis, followed by liquefaction ([Fig. 1-20](#)). Hypoxic death of cells in the CNS

## Pathologic Basis of Veterinary Disease, 4th Edition

results in rapid enzymatic dissolution of the neuropil (liquefaction), likely due to the large amount of cell membranes present. With loss of astrocytes, and because there is normally very little fibrous connective tissue in the CNS, little remains to support the tissue or fill in dead space. The result is a cavity filled with lipid debris and fluid. These cystic areas are cleared of debris by macrophages that become gitter cells (described further in [Chapter 14](#)).

In other tissues, focal infection by pyogenic bacteria leads to release of enzymes from accumulating leukocytes. Early in this process, heterolysis leads to a focal liquid collection of necrotic neutrophils and tissue debris (pus), and the lesion is an abscess that is also a type of liquefactive necrosis. If the abscess persists, loss of fluid or inspissation of the pus results in it becoming more caseous.

### 1.8.1.5.4

#### Gangrene

There are three types of gangrene: dry gangrene, moist gangrene, and gas gangrene. They are included here because the initial lesion is coagulation necrosis. Moist gangrene is defined as an area of necrotic tissue (usually coagulation necrosis), which is further degraded by the liquefactive action of saprophytic bacteria (defined as organisms living in dead organic matter), which usually cause putrefaction (defined as the decomposition of organic matter by microorganisms [i.e., rotten]).

**Fig. 1-20 Liquefactive necrosis. A,** Acute polioencephalomalacia, brain, goat. A thiamine deficiency has resulted in cerebrocortical malacia, which microscopically is liquefaction necrosis and varying degrees of tissue separation (*arrows*). Scale bar = 2 cm. **B,** Cortical necrosis, cerebrum, dog. The pale vertical band in the cerebral cortex contains areas of near total loss of cells and tissue loss termed liquefactive necrosis. The cells in the spaces are gitter cells. Grossly, this band would have a fluid consistency. H&E stain. (**A,** Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University. **B,** Courtesy Dr. L.H. Arp.)

The initial coagulation necrosis can be due to infarction of an extremity (too tight a bandage on a limb, penetrating damage to an artery supplying the leg by a bullet or shrapnel) or of a segment of intestine, or as in the case of the lung, by direct action of aspirated irritants such as medicaments or even ruminal fluid. The saprophytic bacteria contaminate the dead tissue from the local environment (air, skin contaminants, and soil) in the case of a limb, from inhaled air in the lung, and from the adjacent feces in an intestinal infarct.

## Pathologic Basis of Veterinary Disease, 4th Edition

Grossly, tissues become soft, moist, and reddish-brown to black, and if the saprophytic bacteria produce gas, as they usually do, then gas bubbles and a putrid odor from the hydrogen sulfide, ammonia, and mercaptans may occur (Fig. 1-21, A). With time, if death does not supervene from toxemia, gangrenous tissue of the leg and udder will be separated from the normal tissue by inflammation and may slough.

Microscopically, initially areas of coagulation necrosis contain a few proliferating bacteria. These quickly proliferate and produce liquefaction and, depending on the bacteria, gas bubbles. As the lesion progresses, most of the necrotic tissue will be liquefied by saprophytic bacteria and infiltrating neutrophils.

Dry gangrene is really coagulation necrosis secondary to infarction, which is followed by mummification. It involves the lower portion of an extremity (leg), tail, ears, and udder and can be caused by ingested toxins (ergot and fescue poisoning) or cold (frost bite). Ergot produces a marked peripheral arteriolar vasoconstriction and damage to capillaries, which leads to thrombosis and infarction. Fescue poisoning in cattle has a similar pathogenesis and lesions. Exposure to very cold temperatures also causes dry gangrene (frostbite). The pathogenesis involves both direct freezing and disruptions of cells by intracellular and extracellular ice crystal formation and vascular damage leading to ischemia and infarction characterized by coagulation necrosis (see Chapter 17).

23

24

**Fig. 1-21 Gangrenous necrosis. A, Moist gangrene, udder, sheep.** The surrounding tissue is well vascularized, which contributes to the wet and bloody nature of the lesion. Often saprophytic bacteria and clostridia contaminate areas of necrosis. **B, Dry gangrene, fescue toxicity, digits, cow.** Fescue toxicity is a disease in which the blood supply to the distal extremities is lost because of vasoconstriction from the toxic effect on vessels. The dry leathery appearance adjacent to the hooves is termed dry gangrene. There is still some blood in the skin, indicating that at least a partial blood supply has been retained or restored. Note that one of the claws (*right*) has been lost due to the process. (A, Courtesy Dr. C. Wallace, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. B, Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In dry gangrene, after necrosis, the tissues are depleted of water, for example by low humidity, and this dehydration results in mummification. There is no proliferation of bacteria, as dry tissues do not provide an environment favorable for their proliferation and spread. Grossly, the tissue is shriveled, dry, and brown to black (Fig. 1-21, *B*).

Gas gangrene is also an example of bacteria proliferating and producing toxins in necrotic tissue, but in this case the bacteria are anaerobes, usually microbes such as *Clostridium perfringens* and *Clostridium septicum*. These bacteria are introduced by penetrating wounds into muscle or subcutis. The necrotic tissue then provides an anaerobic medium for growth of the clostridia. Another example, with similar lesions, is caused by *Clostridium chauvoei* (blackleg), which, unlike the bacteria of gas gangrene, is not introduced by a penetrating wound but from spores spread hematogenously from the intestine and lodged in muscle. Here they stay until by some mechanism, such as trauma, necrosis occurs and thus produces anaerobic conditions in which the spores can germinate and the bacteria proliferate.

Grossly, affected tissues are dark red to black with gas bubbles and a fluid exudate that may contain blood. Microscopically, the lesions are characterized by coagulation necrosis of muscle, a serohemorrhagic exudate, and gas bubble formation (see Chapter 15). Some authors do not classify the lesions of blackleg as gas gangrene, as it is a result of hematogenously disseminated bacterial spores and not from bacterial contamination of a wound.

1.8.1.6

### NECROSIS OF FAT (FAT NECROSIS)

There are three types of fat necrosis: enzymatic necrosis of fat, traumatic necrosis of fat, and necrosis of abdominal fat of cattle. *Enzymatic necrosis of fat*, also called pancreatic necrosis of fat, refers to the destruction of fat in the abdominal cavity and usually adjacent to the pancreas, by the action of activated pancreatic lipases in pancreatic fluid that has escaped from the duct system of the pancreas (Fig. 1-22).

Traumatic necrosis of fat is seen when adipose tissue is crushed. It occurs in fat adjacent to the pelvic canal of heifers following dystocia, and in subcutaneous tissue that has been injured—for example in the subcutaneous and intramuscular fat over the sternum of recumbent cattle.

Fat necrosis of abdominal fat of cattle is characterized by large masses of necrotic fat in the mesentery, omentum, and retroperitoneally. The cause is unknown and it may not be detected until necropsy. In extreme cases, mesenteric fat may surround the intestine and cause stenosis.

24

25

**Fig. 1-22 Fat necrosis.** **A**, Enzymatic necrosis of fat (fat necrosis), dog with previous bouts of pancreatitis. Necrotic fat often becomes saponified and so grossly the lesion is chalky to gritty and pale white. **B**, Pancreas, dog. Note the large area (*center*) of fat necrosis and saponification (basophilic). H&E stain. (**A**, Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

Grossly affected fat is white, firm, and chalky. Histologically, necrotic fat is not removed by the fat solvents used in the preparation of the paraffin embedded sections. Necrotic adipocytes are eosinophilic but become basophilic if free fatty acids react with  $\text{Ca}^{++}$  to form a soap (saponification of fat).

### 1.8.1.7

#### SEQUELAE TO ONCOTIC NECROSIS

In contrast to apoptosis and postmortem autolysis, necrosis incites a notable inflammatory reaction in the surrounding viable tissue. Therefore the necrotic foci are often surrounded by a well-demarcated band of white blood cells and the hyperemia of inflammation. The purpose is to digest (by heterolytic enzymes of leukocytes) and liquefy the necrotic tissue so that it can be removed by macrophages and diffusion into blood and lymph vessels and replaced by normal tissue (regeneration) or fibrous connective tissue (healing). Healing of an abscess occurs after the sequestered pus is phagocytosed and/or carried off by the lymphatics. The process is greatly hastened by drainage, either by rupture to the outside or by surgical drainage of the abscess. Material not liquified is phagocytosed by macrophages and removed via lymphatics or veins. A fragment of necrotic material, especially bone, may resist degradation and form a sequestrum. This may cause chronic irritation and delay repair.

### 1.8.1.8

#### MORPHOLOGIC APPEARANCE OF POSTMORTEM CHANGES

*Postmortem autolysis* refers to the autolysis of cells occurring after somatic death. These changes are amplified and accelerated by bacterial decomposition from bacteria that have entered the tissue shortly before death or after death (usually by either direct migration from the lumen of the gut of the dead or dying animal, or from the gut into the blood and then disseminated throughout the body by the final beats of the heart).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Postmortem bacterial metabolism and dissolution of host tissues (postmortem decomposition) result in the production of color and texture changes, gas production, and odors collectively termed putrefaction.

*Somatic death* refers to death of the entire body; however, cell types vary greatly in time of viability after cessation of heart beat, respiration, and brain wave activity. In somatic death, many neurons and cardiac myocytes suffer irreversible injury within minutes; kidney and liver cells may survive for an hour; and fibroblasts and bone survive much longer. Interpretation of lesions is usually clouded by changes that occur between the time of death and the time of necropsy (or fixation of tissue). Postmortem autolysis results from total diffuse hypoxia, and cells degenerate as described for hypoxic cell injury. A long death-to-fixation interval can lead to problems in histopathologic diagnosis of necrosis and other lesions; thus keeping postmortem changes to a minimum is important for accurate gross and histopathologic interpretation.

Postmortem changes vary greatly in onset and rate depending on the cause of death, environmental and body temperature, and microbial flora. Cool environmental temperatures and refrigeration (without freezing if possible because freezing induces artefacts such as intracellular and extracellular ice crystals, which disrupt cells and tissues, respectively) inhibit autolysis and delay putrefaction. Animals examined 24 hours after death, after being maintained at 5° C, will have relatively few postmortem changes and artefacts to interpret versus an animal that has been maintained at room temperature for a similar time. An exception is herbivores. In the ruminant forestomach and equine cecum and ascending colon, ingesta will continue to undergo bacterial fermentation after death, with formation of heat and gas. Consequently these animals, even if refrigerated immediately after death, will show considerable intraabdominal postmortem decomposition 24 hours later. High environmental temperatures accelerate autolysis as do fever, high metabolic rate, heat stroke, and exercise before death. Delay in cooling is especially common in fat animals and those with a heavy coat, especially wool. Young and small animals, such as neonates, cool more rapidly than large obese ones. Determining the time since death has occurred can be difficult because of the many factors just listed, influencing the rate of cooling.

In summary, postmortem changes can interfere with accurate interpretation of both gross and histologic changes in tissue. Postmortem changes can be minimized by rapid cooling of the carcass and decreasing the death to tissue fixation time to a minimum. The following are examples of common postmortem changes, with some reference to their sequence of occurrence:

- Rigor mortis is the contraction of muscles occurring after death. It commences 1 to 6 hours after death and persists for 1 to 2 days. When ATP and glycogen (required to relax muscle contraction) are depleted, the contraction is irreversible except by autolysis. Muscular animals often have stronger rigor than those with less muscle mass. High heat and activity before death accelerate the onset of rigor. In animals with cachexia or extreme malnutrition, the energy stores (ATP, glycogen) in the muscles may be so depleted that no contraction of myofibers is possible, and thus these animals do not develop rigor mortis.
- Algor mortis is gradual cooling of the cadaver. Cooling of the carcass depends on temperature of the body at death (e.g., fever, environmental temperature, insulation of the carcass [fat, wool, coverings], body mass, air movement, and other factors) and is difficult to interpret precisely for establishing time of death.
- Livor mortis (hypostatic congestion) (Fig. 1-23) is the gravitational pooling of blood to the down side of the animal. In large vessels, there is clotting followed by separation of blood cells and plasma. This process begins within an hour after death, and the clotted blood can become “fixed” in place (whereby movement of the animal will not influence the distribution of the change) within 12 to 24 hours. It is

## Pathologic Basis of Veterinary Disease, 4th Edition

---

often not appreciated in animals because of pigmented skin or a thick hair coat and thus is most likely to be evident in white-skinned animals with little hair (e.g., white pigs).

- Postmortem clotting (Fig. 1-24) in the heart and vessels occurs within several hours and can be influenced by antemortem changes in blood. Warfarin poisoning and hereditary coagulopathies, for example, will delay or cause failure of blood to clot. Before the blood clots, erythrocytes may settle to the bottom of a large vessel. This results in the clot having two portions: a bottom red mass made up chiefly of erythrocytes and an upper pale yellow mass of clotted serum. The latter type of clot is called a chicken fat clot. This separation depends upon the erythrocyte sedimentation rate (ESR) of the blood. It is high in normal horses and increased in all animals as a systemic inflammatory response.

26

27

Inflammation results in increased plasma fibrinogen, which causes erythrocytes to form stacks (rouleau formation) that sediment more rapidly. Postmortem clots must be distinguished from antemortem mural thrombi and thromboemboli. Postmortem clots are unattached to vessel walls and tend to be shiny and wet and form a perfect cast of vessel lumens. Antemortem mural arterial thrombi are attached to arterial walls, tend to be dry and duller in color, and are laminated with a tail extending downstream from the point of attachment. Antemortem venous thrombi are also attached, but loosely so, and in many cases may closely resemble postmortem clots.

- Hemoglobin imbibition (Fig. 1-25) is a term applied to the red staining of tissue, especially the heart and arteries (particularly evident in the aorta) and veins beginning some hours after death. Once the integrity of the intima is lost, hemoglobin released by lysed erythrocytes penetrates the vessel wall and extends into the adjacent tissue. Hemoglobin staining of the intima can also occur in acute intravascular hemolysis. It is usually very obvious in aborted fetuses that are retained for hours or days after their in utero deaths.

- Bile imbibition (Fig. 1-26) occurs within hours of death. Bile in the gallbladder starts to penetrate its wall and stain adjacent tissue yellowish, and later this may become greenish brown. Tissues involved include the adjacent liver and any intestine in contact with the gallbladder. Sometimes similar changes may be seen near the bile ducts.

- Pseudomelanosis. This is the term used for the blue-green discoloration of the tissue by iron sulfide (FeS) formed by the reaction of hydrogen sulfide (H<sub>2</sub>S) generated by putrefactive bacteria on iron from hemoglobin released from lysed erythrocytes. Because it depends on bacterial action, it usually takes a day or more to develop.

- Softening (Figs. 1-26 and 1-28) of tissue results from autolysis of cells and connective tissue often aided by putrefactive bacteria.

- Bloating (Fig. 1-27) is the result of postmortem bacterial gas formation in the lumen of the GI tract. Herbivores tend to bloat more rapidly and severely than carnivores. In ruminants the rumen can become markedly distended by gas within hours of death, and this can be so severe as to rupture the diaphragm. The rate of gas formation depends upon the diet, the substrate for the bacteria, and the temperature. Postmortem bloat can sometimes be difficult to distinguish from antemortem bloat (ruminal tympany) in ruminants. Bacteria disseminated hematogenously from the GI tract shortly before death can lodge in a variety of tissues and produce gas (postmortem emphysema).

27

- Organ displacement occurs following distention of the viscera; for example, distention of the rumen by gas from fermentation can cause increased intraabdominal pressure, which can result in displacement of abdominal viscera, rectal prolapse, and compression of the diaphragm, which then compresses the

28

## Pathologic Basis of Veterinary Disease, 4th Edition

---

thoracic viscera. The latter can result in the expulsion of frothy fluid, originally in the lungs, from the mouth and nose.

- Pale foci subserosally on the liver ([Fig. 1-28](#)) can result from two causes: increased intraabdominal pressure, which squeezes blood from these areas (e.g., pressure from the overlying ribs can leave their imprints on the liver), and bacterial action. Under very hot conditions, pale areas can appear on the surface of the bovine liver within hours of death. Histologically these areas resemble coagulation necrosis in which there are extremely numerous bacteria. Presumably these bacteria have been disseminated agonally from the gut into the portal vein.
- Mucosal sloughing occurs rapidly in the rumen, often within a few hours as a result of the enzymes within the ingesta and the low rate of cooling.
- Lens opacity ([Fig. 1-29](#)) occurs when the carcass is very cold or frozen. The change will reverse to normal transparency on warming, but it can be confused with cataracts in cold carcasses.

**Fig. 1-23 Livor mortis, pig.** Note red to purple staining of the skin on the right side, the side on which the pig was lying when it died. This color change is termed livor mortis or hypostatic congestion. The pale white areas are pressure points on the down side into which blood could not flow after death. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Fig. 1-24 **Postmortem clot, dog.** The postmortem clot is pale white to yellow (chicken fat clot) in some areas and shiny red (currant jelly clot) in others. Note how it conforms to the shape of the lumen of the vessels from which it was removed. (Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

Fig. 1-25 **Imbibition of hemoglobin, viscera, pig that has been dead for several hours before being necropsied.** Note the pink color on the serosal surfaces of the stomach and small intestine. This is termed imbibition of hemoglobin and is due to staining by hemoglobin that has seeped out of autolyzed red blood cells. (Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

Fig. 1-26 **Postmortem autolysis.** Cross sections of livers from three different pigs at different stages of postmortem autolysis. The section on the right has green staining around the bile ducts due to leakage of bile into the surrounding parenchyma after death (bile imbibition). All of these livers are softer than normal, but the one on the left is notably softer, another characteristic of autolytic tissue. (Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

Fig. 1-27 **Postmortem bloat or emphysema.** Cow killed by lightning several hours earlier. When animals die, especially ruminants, the bacteria in the GI tract continue to grow and produce gas. Rumen microbes may produce very large amounts of gas causing the carcass to swell tremendously. (*Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

Fig. 1-28 **Postmortem autolysis.** Pig livers at various intervals after death. Pale foci on the middle liver are due to blood being forced out of the parenchyma by intestinal swelling (intestinal imprints) and from pressure from the overlying ribs (rib imprints). Multiple small pale foci can sometimes be caused by colonies of postmortem bacteria and can be confused with antemortem necrosis. (*Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.*)

Fig. 1-29 **Postmortem autolysis, eye, lens, calf.** Note that the cornea is clear. The cloudiness of the lens is due to cooling or freezing and is reversible as the carcass warms up. It should not be confused with cataracts. (Courtesy Dr. P.N. Nation, University of Alberta; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

### 1.8.2 CELL DEATH BY APOPTOSIS

*Apoptosis* and *programmed cell death* have been used virtually synonymously and refer to individual cell death in a variety of processes. Common to both is the initiation of a self-induced cell death process some refer to as cellular suicide. Although there is much overlap in cellular mechanisms, the term *programmed cell death* should be reserved for physiologic cell death that occurs in developing animals (embryogenesis and normal growth). Production of the keratinized outer layer of skin, for example, involves programmed cell death. For those circumstances in which pathologic cell death occurs with shrinkage first as a feature, *apoptosis* or *apoptotic necrosis* is more appropriately used. Apoptosis occurs in a variety of pathologic circumstances, including viral

28

29

Fig. 1-30 **Mechanisms of apoptosis.** Labeled (1) are some of the major inducers of apoptosis. These include specific death ligands (tumor necrosis factor [TNF] and Fas ligand), withdrawal of growth factors or hormones, and injurious agents (e.g., radiation). Some stimuli (such as cytotoxic cells) directly activate execution caspases (right). Others act by way of adapter proteins and initiator caspases, or by mitochondrial events involving cytochrome c. (2) Control and regulation are influenced by members of the Bcl-2 family of proteins, which can either inhibit or promote the cell's death. (3) Executioner caspases activate latent cytoplasmic endonucleases and proteases that degrade nuclear and cytoskeletal proteins. This results in a cascade of intracellular degradation, including fragmentation of nuclear chromatin and breakdown of the cytoskeleton. (4) The end result is formation of apoptotic bodies containing intracellular organelles and other cytosolic components; these bodies also express new ligands for binding and uptake by phagocytic cells. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

1.8.2.1

### MECHANISMS OF APOPTOSIS\*

Mechanisms of programmed cell death and apoptosis have been extensively researched within the last decades. A variety of stimuli result in a self-programmed, genetically determined, energy-dependent sequence

## Pathologic Basis of Veterinary Disease, 4th Edition

of molecular events involving initiation by cell signaling, control and integration by regulatory molecules, a common execution phase by caspase family genes, and dead cell removal. Some of these mechanisms are initiated by inflammatory mediators such as tumor necrosis factor (TNF) and the Fas ligand (FasL). Others involve deprivation of growth factors, mitochondrial damage, DNA damage, or immune stimulation (Fig. 1-30).

The process of apoptosis may be divided into an initiation phase, during which caspases become catalytically active, and an execution phase, during which these enzymes act to cause cell death. Initiation of apoptosis occurs principally by signals from two distinct but convergent pathways: the extrinsic, or receptor-initiated, pathway and the intrinsic, or mitochondrial, pathway. Both pathways converge to activate caspases. We will describe these two pathways separately because they involve largely distinct molecular interactions, but it is important to remember that they may be interconnected at numerous steps.

\* Portions of this section are from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

### 1.8.2.2

#### THE EXTRINSIC (DEATH RECEPTOR–INITIATED) PATHWAY

This pathway is initiated by engagement of cell surface death receptors on a variety of cells. Death receptors are members of the TNF receptor family that contain a cytoplasmic domain involved in protein-protein interactions that is called the death domain because it is essential for delivering apoptotic signals. (Some TNF receptor family members do not contain cytoplasmic death domains; their role in triggering apoptosis is much less established). The best-known death receptors are the type 1 TNF receptor (TNFR1) and a related protein called Fas (CD95), but several others have been described. The mechanism of apoptosis induced by these death receptors is well illustrated by Fas (Fig. 1-31). When Fas is cross-linked by its ligand, membrane-bound FasL, three or more molecules of Fas come together, and their cytoplasmic death domains form a binding site for an adapter protein that also contains a death domain and is called FADD (Fas-associated death domain). FADD is attached to the death receptors, which in turn bind an inactive form of caspase-8 (and, in humans, caspase-10), again via a death domain. Multiple procaspase-8 molecules are thus brought into proximity, and they cleave one another to generate active caspase-8. The enzyme then triggers a cascade of caspase activation by cleaving and thereby activating other procaspases, and the active enzymes mediate the execution phase of apoptosis (discussed later). This pathway of apoptosis can be inhibited by a protein called FLIP, which binds to procaspase-8 but cannot cleave and activate the enzyme because it lacks enzymatic activity. Some viruses and normal cells produce FLIP and use this inhibitor to protect infected and normal cells from Fas-mediated apoptosis. The sphingolipid ceramide has been implicated as an intermediate between death receptors and caspase activation, but the role of this pathway is unclear and remains controversial.

**Fig. 1-31 The extrinsic (death receptor-initiated) pathway of apoptosis, illustrated by the events following Fas engagement.** *FADD*, Fas-associated death domain; *FasL*, Fas ligand. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 1.8.2.2.1

#### The Intrinsic (Mitochondrial) Pathway

This pathway of apoptosis is the result of increased mitochondrial permeability and release of proapoptotic molecules into the cytoplasm, without a role for death receptors. Growth factors and other survival signals stimulate the production of antiapoptotic members of the Bcl-2 family of proteins. This family is named after Bcl-2, which was identified as an oncogene in a B-lymphocyte lymphoma and is homologous to the *Caenorhabditis elegans* protein, Ced-9. There are more than 20 proteins in this family, all of which function to regulate apoptosis; the two main antiapoptotic ones are Bcl-2 and Bcl-x. These antiapoptotic proteins normally reside in mitochondrial membranes and the cytoplasm. When cells are deprived of survival signals or subjected to stress, Bcl-2 and/or Bcl-x are lost from the mitochondrial membrane and are replaced by proapoptotic members of the family, such as Bak, Bax, and Bim. When Bcl-2/Bcl-x levels decrease, the permeability of the mitochondrial membrane increases, and several proteins that can activate the caspase cascade leak out (Fig. 1-32). One of these proteins is cytochrome *c*, well known for its role in

## Pathologic Basis of Veterinary Disease, 4th Edition

mitochondrial respiration. In the cytosol, cytochrome *c* binds to a protein called Apaf-1 (apoptosis activating factor-1, homologous to Ced-4 in *Caenorhabditis elegans*), and the complex activates caspase-9. (Bcl-2 and Bcl-x may also directly inhibit Apaf-1 activation, and their loss from cells may permit activation of Apaf-1.) Other mitochondrial proteins, such as apoptosis inducing factor (AIF), enter the cytoplasm, where they bind to and neutralize various inhibitors of apoptosis, whose normal function is to block caspase activation. The net result is the initiation of a caspase cascade. Thus the essence of this intrinsic pathway is a balance between proapoptotic and protective molecules that regulate mitochondrial permeability and the release of death inducers that are normally sequestered within the mitochondria. There is quite a lot of evidence that the intrinsic pathway of apoptosis can be triggered without a role for mitochondria. Apoptosis may be initiated by caspase activation upstream of mitochondria, and the subsequent increase in mitochondrial permeability and release of proapoptotic molecules amplify the death signal. However, these pathways of apoptosis involving mitochondria-independent initiation are not well defined. We have described the extrinsic and intrinsic pathways for initiating apoptosis as distinct, but there may be overlaps between them. For instance, in hepatocytes, Fas signaling activates a proapoptotic member of the Bcl family called Bid, which then activates the mitochondrial pathway. It is not known if such cooperative interactions between apoptosis pathways are active in most other cell types.

30

31

**Fig. 1-32 The intrinsic (mitochondrial) pathway of apoptosis.** Death agonists cause changes in the inner mitochondrial membrane, resulting in the mitochondrial permeability transition (MPT) and release of cytochrome *c* and other proapoptotic proteins into the cytosol, which activate caspases. AIF, Apoptosis-inducing factor. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

1.8.2.3

### THE EXECUTION PHASE

This final phase of apoptosis is mediated by a proteolytic cascade, toward which the various initiating mechanisms converge. The proteases that mediate the execution phase are highly conserved across species and belong to the caspase family, as previously mentioned. They are mammalian homologues of the Ced-3 gene in *Caenorhabditis elegans*. The term *caspase* is based on two properties of this family of enzymes: The “c” refers to a cysteine protease (i.e., an enzyme with cysteine in its active site), and “aspase” refers to the unique ability of these enzymes to cleave aspartic acid residues. The caspase family, now including more than 10 members, can be divided functionally into two basic groups: initiator and executioner, depending on the order in which they are activated during apoptosis. Initiator caspases, as we have seen, include caspase-8 and caspase-9. Several caspases, including caspase-3 and caspase-6, serve as executioners. Like many proteases, caspases exist as inactive proenzymes, or zymogens, and must undergo an activating cleavage for apoptosis to be initiated. Caspases have their own cleavage sites that can be hydrolyzed not only by other caspases but also autocatalytically. After an initiator caspase is cleaved to generate its active form, the enzymatic death program is set in motion by rapid and sequential activation of other caspases. Execution caspases act on many cellular components. They cleave cytoskeletal and nuclear matrix proteins and thus disrupt the cytoskeleton and lead to breakdown of the nucleus. In the nucleus, the targets of caspase activation include proteins involved in transcription, DNA replication, and DNA repair. In particular, caspase-3 activation converts a cytoplasmic DNAase into an active form by cleaving an inhibitor of the enzyme; this DNAase induces the characteristic internucleosomal cleavage of DNA, described earlier.

31

32

**Fig. 1-33 Apoptosis, cytoarchitecture of cells, pancreas, rat.** Individual acinar cells are shrunken and their chromatin condensed and fragmented (*arrows*). Cytoplasmic blebs are found in adjacent cells. Inflammation is absent. H&E stain. (Courtesy Dr. M.A. Wallig, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

1.8.2.4

### MORPHOLOGIC APPEARANCE OF APOPTOSIS

Morphologically, apoptotic cells have condensed chromatin and cytoplasm, and fragments of them are often found in adjacent or phagocytic cells (Fig. 1-33). Because single cells are dead, gross changes (and even microscopic changes) are usually not obvious. In addition, because the cell fragments into membrane-bound particles, phagocytosis occurs without the inflammation that is so often seen in necrosis.

Although typically discussed separately, necrosis by oncosis and apoptosis can be seen within the same tissue due to the same agent (Fig. 1-34). Cell injury by a chemical, for example, that injures mitochondria may release cytochrome *c* and initiate the apoptosis program. Cells with more severely affected mitochondria may die from swelling or oncosis.

The histopathologic characteristics of apoptosis are listed next:

- Individual cells are shrunken.
- Chromatin is condensed.
- Cytoplasm is fragmented.
- Cytoplasmic buds often containing a fragment of nucleus form on the surface, separate, and are found in adjacent cells and phagocytes as apoptotic bodies.
- Inflammation is absent.

**Fig. 1-34 Necrosis and apoptosis, mouse hepatitis virus infection, liver, mouse.** This disease causes hepatocyte death, typically by oncotic necrosis but sometimes by apoptosis. Note areas of coagulation necrosis in the lower left and apoptotic bodies in the center, some of which have been taken up by adjacent hepatocytes (*arrows*). H&E stain. (Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

# Pathologic Basis of Veterinary Disease, 4th Edition

## 1.9 CHRONIC CELL INJURY AND CELL ADAPTATION

As mentioned previously in the discussion of cell swelling and necrosis, cells respond to injury (or stress) in three possible major ways: (1) adaptation, (2) reversible injury with or without degeneration, and (3) death. Sublethal injury to a cell over time can lead to a variety of cell alterations. Cells may adapt by producing more cells (hyperplasia) or by producing more organelles, leading to an increase in size (hypertrophy); in some cases adaptation results in fewer organelles and a decrease in cell and tissue size (atrophy). Cells may degenerate in a variety of ways, some of which involve the accumulation of excess normal or abnormal substances. Impaired function may result, and morphologic changes in the cell and tissue may give a clue as to the cause of the cell injury.

### 1.9.1 SUBLETHAL INJURY AND SUBCELLULAR CHANGES

#### 1.9.1.1 AUTOPHAGOCYTOSIS

Autophagocytosis is the uptake and intracellular degradation of damaged or effete organelles. Cells with sublethal injury often have various amounts of damaged organelles. As in organized societies, the cell has a system to clean up after a “storm.” In autophagy, portions of the cytoplasmic matrix and its damaged organelles are enveloped by cell membranes to form autophagosomes, which subsequently fuse with lysosomes (Fig. 1-35). When phagocytic white cells ingest dead or dying cells, the process is very similar and termed heterophagy. Autophagy is a common reaction of sublethally injured cells, cells undergoing cyclic physiologic regression (glands), and in atrophy due to many causes. Recent evidence suggests that autophagocytosis pathways may result in a distinct type of cell death.

32

33

By light microscopy, autophagic vacuoles may appear as eosinophilic inclusions (see Intracellular Hyaline Proteins) and are common in the liver and kidney. As digestion progresses, electron-dense and lamellar debris is formed. Some vacuoles are evicted from the cell by exocytosis; others remain as residual bodies, and the contents form lipofuscin, the so-called wear-and-tear pigment.

Misfolded proteins or those otherwise altered occur in a variety of circumstances within the cell, both normally and in disease states. These proteins may be repaired by chaperones, or they may be degraded by the ubiquitin-proteasome pathway. The targeted proteins are conjugated to ubiquitin (one of several heat shock proteins) that through a cascade results in polyubiquitination and direction of the protein into a proteasome, a multisubunit complex with a catalytic core that degrades the protein for removal. Removal of all sorts of proteins, including cell signaling molecules, allows proper control of cell function, growth, and replication. This pathway also plays a role in both activation and inhibition of apoptosis as well as in sublethal injury.

#### 1.9.1.2 ADAPTIVE CHANGES LEADING TO CHANGE IN CELL SIZE, NUMBER, OR APPEARANCE

Adaptive changes to cell stress or injury can lead to an increase in the size of a tissue or organ (by hyperplasia and/or hypertrophy), a decrease in tissue and cell size (atrophy), or a change to a different cell type (metaplasia) (Fig. 1-36). *Hypertrophy* is an increase in the size of cells or organs. *Hyperplasia* is an increase in the number of cells in a tissue or organ. The two often occur together as an adaptive change and are considered positive responses to injury or stress.

## Pathologic Basis of Veterinary Disease, 4th Edition

1.9.1.2.1

### Hypertrophy

In simple cellular hypertrophy, the number of cells does not increase. Cells synthesize more organelles, and cell enlargement occurs. The histologic architecture of the organ is normal, but cells are bigger. Hypertrophy can occur in most organs and tissues but tends to occur in cells that undergo little replication (i.e., stable or permanent cells). It is most common in striated muscle. Smooth muscle may have hypertrophy and hyperplasia. Causes of hypertrophy usually involve demands for increased function (e.g., the increased work load on a muscle and resultant hypertrophy of that muscle in weight lifters).

**Fig. 1-35 Autophagy and heterophagy.** Schematic representation of heterophagy (*left*) and autophagy (*right*). The mechanisms are similar for processing cell debris, both from intrinsic sources and extrinsic sources (heterophagy). (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The size and configuration of organelles reflect the work requirements of the cell. Chronic exposure to drugs such as phenobarbital, dilantin, and alcohol lead to enlargement of the SER in hepatocytes. SER contains the mixed oxidase enzyme systems that function to catabolize these substances. The increased size of the Golgi complex and RER are a reflection of a need for synthesis of extracellular proteins (e.g., immunoglobulin, collagen, and secretions). These organelles increase in size by duplication of membranes. The number of mitochondria adjusts to the ATP requirements of the cell. The size of nucleoli and proportion of euchromatin also reflect the synthetic activity of the cell.

## Pathologic Basis of Veterinary Disease, 4th Edition

Physiologic hypertrophy is common and expected following work. Compensatory hypertrophy is a response to the loss of a part of an organ or one of the paired organs or from obstruction of the lumen of a hollow muscular organ. For example, hypertrophy occurs in one kidney after the loss of the opposite kidney. The kidney enlarges due to the increased length of nephrons and not to the increased numbers of nephrons. Functional capacity increases with the increased size. Hypertrophy of the right ventricle of the heart because of stenosis of the pulmonary outflow tract is another example of compensatory hypertrophy (Fig. 1-37).

Hypertrophy is common, protective, limited, and reversible and may rarely cause harm to adjacent structures. Hypertrophy may not always be useful. In myocardial hypertrophy, enlargement of myofibers may occur with a corresponding increase in intercellular stroma, making the myocardium stiff. In addition, the blood supply may not increase adequately to serve the increased mass of myocytes, and this results in hypoxic injury. The term *hypertrophy* is used in gross pathology to describe lesions that involve gross enlargement of an organ regardless of cause.

33

34

Fig. 1-36 Adaptive changes in epithelium.

Cellular mechanisms leading to hypertrophy vary by tissue and cause, and details are lacking for most entities. Growth factors likely play a role in altering gene expression in many circumstances, whereas in myofiber hypertrophy, the type of mechanical stress can influence the way the muscle enlarges, for example with increased mitochondria, required for oxidative metabolism in endurance training.

34

35

Hypertrophy of the uterus results from estrogen binding of cytosolic receptors that in turn lead to activation of genes leading to muscle protein production. These specific changes and others all are likely due to activation of specific genes.

**Fig. 1-37 Hypertrophy, heart, dog.** **A**, Narrowing of the pulmonary outflow track caused by pulmonic valve stenosis has forced the right ventricle to contract with much more pressure. This increased workload has caused hypertrophy of the wall of the right ventricle, which is much thicker here than it would normally be. **B**, Note the increased size (hypertrophy) of myocytes in the overworked heart muscle. (**A** and **B**, Courtesy Dr. L. Miller, Atlantic Veterinary College, University of Prince Edward Island; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

### 1.9.1.2.2

#### Hyperplasia

Because hyperplasia is an increase in the number of cells, increased mitotic division is implied. Hyperplasia increases the size of a tissue, an organ, or part of an organ and may appear grossly as hypertrophy. It is a common change. Microscopically, cells resemble normal cells but are increased in numbers. Hyperplastic cells may also be increased in size (i.e., hypertrophic).

The ability of different adult cell types to undergo hyperplasia varies. Labile cells—those that routinely proliferate in normal circumstances, such as those of the epidermis, intestinal epithelium, and bone marrow cells—readily become hyperplastic. Permanent cells such as neurons and cardiac and skeletal muscle myocytes have very little capacity to regenerate or become hyperplastic in most situations. Stable cells, such as bone, cartilage, and smooth muscle, are intermediate in their ability to become hyperplastic.

Hyperplasia is traditionally divided into physiologic hyperplasia and pathologic hyperplasia. Physiologic hyperplasia is usually either hormonal or compensatory. Hormonal hyperplasia includes conditions such as increased mammary gland epithelial proliferation before lactation and enlargement of the pregnant uterus. Compensatory hyperplasia, or regeneration, occurs after a portion of an organ is lost. For example, if the skin is abraded, the basal layer of the epidermis undergoes mitosis to regenerate superficial layers. Removal of part of the liver can cause mitosis in the remaining hepatocytes resulting in the restoration of the liver to its normal size. This regenerative process takes as little as 2 weeks in rats after partial hepatectomy.

**Fig. 1-38 Hyperplasia, thyroid goiter, goat.** **A**, Deficiency of maternal dietary iodine during pregnancy has resulted in hyperplasia (and hypertrophy) of thyroid follicular epithelial cells in this neonatal goat and thus results in a symmetric enlargement of the glands (goiter). **B**, Thyroid follicular epithelial cells from a normal thyroid gland. H&E stain. **C**, Thyroid follicular epithelial cells from a case of thyroid goiter. Note the increased number (and size) of the follicular epithelial cells. H&E stain. (**A**, Courtesy Dr. O. Hedstrom, College of Veterinary Medicine, Oregon State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B** and **C**, Courtesy Dr. B. Harmon, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Pathologic hyperplasia is often caused by excessive hormonal stimulation of target cells or chronic irritation. Cystic endometrial hyperplasia of the canine uterus as a result of prolonged progesterone influence is common. Microscopically, there is folding of increased numbers of epithelial cells into glands and onto the lumen surface. The mucosa thickens and may trap or impair secretions, causing dilation of glands and cyst formation within the mucosa. The process is reversible if the stimulus is removed.

Pathologic hyperplasia may cause diffuse enlargement of an organ, such as in benign prostatic hyperplasia in dogs and in goiter (hyperplasia of the thyroid gland) (Fig. 1-38), or be localized as nodular hyperplasia. Nodular hyperplasia may occur without known cause and occurs in the spleen, liver, and pancreas of old dogs. One must differentiate hyperplasia, particularly nodular hyperplasia, from neoplasia.

The significance of hyperplasia usually lies in determining its cause. If it is hormonal in origin, the disturbance in the source organ should be determined. If chronic irritation is the cause, determining the agent is often important. Hyperplasia is usually induced by known stimuli. It is a controlled process that stops when the stimulus ceases, can serve a useful purpose (e.g., repair defects, compensate for tissue loss, prepare for increased function, and aid in protection), and is subject to regular growth controls. These

35

36

## Pathologic Basis of Veterinary Disease, 4th Edition

features are not part of neoplastic processes, which otherwise may be similar to hyperplastic changes in appearance and behavior.

Cellular mechanisms of hyperplasia vary in details depending on the cell affected and the cause. There are multiple controls as to whether or not a cell enters the replication cycle. In some circumstances hormones trigger cell replication, whereas in others growth factors, increased receptors for growth factors, and activation of cell signaling pathways may all have a role. In some circumstances cytokines are important. Ultimately, transcription factors may influence the expression of a new cadre of genes leading to cell proliferation. In regeneration for restitution of parenchyma to normal amounts (see later discussion), stem cells turn on and lead to appropriate cell replication.

### 1.9.1.2.3

#### Metaplasia

Metaplasia is a reversible change in which one adult cell type is replaced by another adult cell type of the same germ line (Fig. 1-39). Usually, specialized epithelium is replaced by less specialized epithelium. One adult cell type does not transform into another type of adult cell. It is the less-differentiated reserve or stem cells that differentiate along a different line. For example, in cigarette smokers, chronic irritation of the normal columnar ciliated epithelium of the trachea and bronchial tree causes it to be replaced by focal or diffuse areas of stratified squamous epithelium. The squamous cells are more resistant to injury but are less protective to the lung, and, as they lack cilia, there is decreased clearance of mucus.

Metaplasia is often but not always an adaptive change to withstand adverse environmental conditions and is reversible if the cause is removed. Epithelial metaplasia is commonly to squamous epithelium and is usually a result of chronic irritation, but it can have other causes (e.g., avitaminosis A). Metaplasia in mesenchymal tissue is less clearly adaptive and is usually a response to change of microenvironment of cells, such as oxygen tension. One type of mesenchymal tissue changes to another; fibrous tissue changes to cartilage or bone, for example.

**Fig. 1-39 Metaplasia.** Schematic diagram of columnar to squamous metaplasia. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The following are some examples and causes of metaplasia:

- Chronic irritation from particles and chemicals in the lungs of smokers may cause the normal cuboidal and columnar epithelium of airways to become stratified squamous.
- Vitamin A deficiency causes squamous metaplasia of the transitional epithelium of the urinary tract, cuboidal and columnar epithelial cells lining the ducts within the salivary glands, and the epithelium of the mucous glands of esophageal mucosa in birds (Fig. 1-40).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Estrogen toxicity, among other things, causes squamous metaplasia of the urinary tract and prostate.
- Healing of glandular epithelium following mastitis may at first be squamous.
- Squamous metaplasia of salivary, biliary, and pancreatic ducts can occur if they are blocked by stones in the lumen.
- Metaplastic bone (osseous metaplasia) occasionally occurs in injured soft tissue.
- Myeloid metaplasia (extramedullary hematopoiesis) in adult spleens and livers occurs commonly after bone marrow injury or insufficiency.
- Metaplasia occurs in some tumors, such as mixed mammary gland tumors of dogs.

Metaplasia is reversible (usually) if the cause is withdrawn. It may, however, be preneoplastic—for example, in the lungs of smokers where it appears before transformation to squamous cell carcinoma.

Cellular mechanisms leading to metaplasia vary. Vitamin A is important in normal differentiation of mucus secreting epithelium by yet unspecified mechanisms. When vitamin A is deficient, these cells differentiate along squamous lines. Estrogen causes differentiation along squamous lines in specific sex hormone responsive epithelia. Growth factors and other trophic substances presumably can influence differentiation along certain pathways from stem cells and ECM (extracellular matrix) can play an important role. How these metaplastic changes take place in response to injury is less clear.

### 1.9.1.2.4

#### Atrophy

Atrophy is the decrease in size or amount of a cell, tissue, or organ after normal growth has been reached (Fig. 1-41). It is due to the decreased number and/or size of cells. It may affect virtually any organ or part of an organ. It is a regressive change usually due to gradual and continuous injury. Some causes and examples of atrophy are:

- Deficient nutritive supply. Starvation and especially a decreased blood supply. For example, liver atrophy results from decreased blood flow through the portal vein (Fig. 1-42). 36
- Decreased workload. For example, muscle fibers atrophy in sedentary people. 37
- Disuse. Muscles in a limb that is in a cast atrophy.
- Denervation. Muscle fibers decrease in size if a nerve is severed.
- Pressure. Atrophy, degeneration, and necrosis occur adjacent to tumors because of pressure and compromised blood supply.
- Loss of endocrine stimulation. Atrophy of the zona fasciculata of the adrenal follows prolonged steroid therapy.

Fig. 1-40 **Squamous metaplasia, esophagus, parrot.** **A**, The esophageal mucosa has multiple white raised nodules from squamous metaplasia of mucosal glands. Metaplasia arose from the lack of dietary vitamin A (avitaminosis A). **B**, Note the squamous metaplasia of the esophageal glands. Vitamin A is necessary for maintenance of the normal epithelium. Avitaminosis A results in the replacement of normal mucosal epithelium and goblet cells in the glands by keratinized stratified squamous epithelium. H&E stain. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 1-41 Atrophy, right thyroid gland on trachea, dog.** **A**, The right thyroid gland is extremely small and difficult to discern. Only small pieces of thyroid tissue remain (*arrows*). **B**, The thyroid gland is extremely small, follicles are atrophic and of varied sizes, and colloid has a low concentration of thyroglobulin protein (*pale pink color*). Note that supporting stroma has been replaced by fat cells. The parathyroid gland (*right*) is of normal size. H&E stain. (**A**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

Involution is the decrease in size of a tissue caused by reduction in the number of cells (usually by apoptosis) and is usually used to refer to physiologic processes. For example, the thymus involutes with age, and many tissues become smaller because of senile involution. The uterus involutes after parturition, and its smooth muscle cells decrease notably in size and number.

The pathogenesis of atrophy implies an adverse environment. Cells regress to a smaller cell size and survive, but with decreased function. The general cause is inadequate cellular nutrition for any reason. Synthesis of proteins is exceeded by degradation or loss.

**Fig. 1-42 Atrophy, liver, dog.** **A**, Note the small size (up under the rib cage) but normal color of the liver in this dog and the anomalous size of the caudal vena cava in the mesentery (i.e., shunt between the portal vein and the systemic circulation). This shunt caused bypassing of blood from the liver. The reduction in blood flow to the liver causes decreased nutrients (hepatocyte trophic factors) to the hepatocytes and therefore decreased size of hepatocytes. **B**, Normal liver. H&E stain. **C**, Liver, atrophy. Hepatocytes are smaller and narrower than those in the normal liver (**B**). As a consequence, the sinusoids are correspondingly wider. H&E stain. (**A**, Courtesy Dr. J. Sagartz, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **C**, Courtesy Dr. R.K. Myers, College of Veterinary Medicine, Iowa State University.)

37

Autophagocytosis, lysosomes, and the ubiquitin proteasome pathway (see earlier discussion under Sublethal Injury and Subcellular Changes) may all play a role in decreasing the organelle and protein content of a cell. The actual triggers and cellular mechanisms are unclear for many circumstances. Atrophy may resolve if the cause is removed. It may persist as is, with or without harm to the organism, or it may progress.

38

Atrophied organs grossly have a decreased weight and volume, may have a loose covering membrane (e.g., wrinkled skin), have tortuous blood vessels too large for the volume of tissue, and often are firmer due to fibrosis. Microscopically, cells are smaller and/or reduced in number. Ultrastructurally there are fewer mitochondria, less ER, and fewer myofilaments (muscle), and often there is an increase in autophagic vacuoles and maybe lipofuscin.

Serous atrophy of fat is a very important necropsy finding, as it may indicate starvation. Grossly, fat deposits are completely or partially depleted, and a clear or yellowish gelatinous material remains. Histologically, adipocytes are smaller, and interstitial hyaluronic acid mucopolysaccharides are increased.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

It is most evident in the epidural and perirenal fat, but may affect any fat depot including bone marrow. The cause of starvation may be virtually anything: malnutrition, malabsorption, chronic infection, parasitism, neoplasia, etc. It is common in neonates, often due to mismothering.

### 1.10 INTRACELLULAR ACCUMULATIONS\*

One of the manifestations of metabolic derangements in cells is the intracellular accumulation of abnormal amounts of various substances (Fig. 1-43). The stockpiled substances fall into three categories: (1) a normal cellular constituent accumulated in excess, such as water, lipids, proteins, and carbohydrates; (2) an abnormal substance, either exogenous, such as a mineral or products of infectious agents, or endogenous, such as a product of abnormal synthesis or metabolism; or (3) a pigment. These substances may accumulate either transiently or permanently, and they may be harmless to the cells, but on occasion they are severely toxic. The substance may be located in either the cytoplasm (frequently within phagolysosomes) or the nucleus. In some instances, the cell may be producing the abnormal substance, and in other cells they may be merely storing products of pathologic processes occurring elsewhere in the body.

Many processes result in abnormal intracellular accumulations, but most accumulations are attributable to three types of abnormalities.

1. A normal endogenous substance is produced at a normal or increased rate, but the rate of metabolism is inadequate to remove it. An example of this type of process is fatty change in the liver because of intracellular accumulation of triglycerides (described in a later section). Another example is the appearance of reabsorption protein droplets in the epithelial cells of renal proximal tubules because of increased leakage of protein from the glomerulus. 38 39
2. A normal or abnormal endogenous substance accumulates because of genetic or acquired defects in the metabolism, packaging, transport, or secretion of these substances. One example is the group of conditions caused by genetic defects of specific enzymes involved in the metabolism of lipid and carbohydrates resulting in intracellular deposition of these substances, largely in lysosomes in so-called storage diseases. Another is  $\alpha_1$ -antitrypsin deficiency, in which a single amino acid substitution in the enzyme results in defects in protein folding and accumulation of the enzyme in the ER of the liver in the form of globular eosinophilic inclusions.
3. An abnormal exogenous substance is deposited and accumulates because the cell has neither the enzymatic machinery to degrade the substance nor the ability to transport it to other sites. Accumulations of carbon particles and nonmetabolizable chemicals such as silica particles are examples of this type of alteration.

**Fig. 1-43 Mechanisms of intracellular accumulations.** **A**, Abnormal metabolism, as in fatty change in the liver; **B**, mutations causing alterations in protein folding and transport, as in  $\alpha_1$ -antitrypsin deficiency; **C**, deficiency of critical enzymes that prevent breakdown of substrates that accumulate in lysosomes, as in lysosomal storage diseases; and **D**, inability to degrade phagocytosed particles, as in hemosiderosis and carbon pigment accumulation. (**A** through **D**, From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Whatever the nature and origin of the intracellular accumulation, it implies the storage of some product by individual cells. If the overload is due to a systemic derangement and can be brought under control, the accumulation is reversible. In genetic storage diseases, accumulation is progressive, and the cells may become so overloaded as to cause secondary injury, leading in some instances to death of the tissue and the patient.

### 1.10.1 LIPIDS

#### 1.10.1.1 HEPATIC LIPIDOSIS (FATTY LIVER, FATTY CHANGE, HEPATIC STEATOSIS)

All major classes of lipids can accumulate in cells: triglycerides, cholesterol/cholesterol esters, and phospholipids. Phospholipids are components of the myelin figures found in necrotic cells. In addition, abnormal complexes of lipids and carbohydrates accumulate in the lysosomal storage diseases.

Lipidosis is the accumulation of triglycerides and other lipid metabolites (neutral fats and cholesterol) within parenchymal cells. Although it occurs in heart muscle, skeletal muscle, and the kidney, clinical manifestations are most commonly detected as alterations in liver function (elevated liver enzymes, icterus) because the liver is the organ most central to lipid metabolism.

Hepatic lipidosis, the prototype example of this type of cellular degeneration, can occur as the result of one of five mechanisms:

1. Excessive delivery of free fatty acids either from the gut or from adipose tissue
2. Decreased  $\beta$ -oxidation of fatty acids to ketones and other substances because of mitochondrial injury (toxins, hypoxia)
3. Impaired synthesis of apoprotein (CCl<sub>4</sub> toxicity, aflatoxicosis)
4. Impaired combination of triglycerides and protein to form lipoprotein (uncommon)
5. Impaired release (secretion) of lipoproteins from the hepatocyte (uncommon)

The underlying pathogenesis of hepatic lipidosis centers on the biochemical pathways of free fatty acid formation and metabolism. Free fatty acids, derived from triglycerides, provide a large component of the basal energy needs for parenchymal cells. They are obtained directly from the diet through digestive processes, from chylomicrons in the blood, or from adipose cells in body fat stores (adipose tissue). Chylomicrons transport dietary lipids consisting predominately of triglycerides from the alimentary system to the liver, muscle, and adipose tissue. Lipoprotein lipase and other proteins act synergistically within the chylomicron to free fatty acids from triglycerides for their use as an energy source. In the liver, free fatty acids are esterified to triglycerides, converted into cholesterol or phospholipids, or oxidized to ketones. Triglycerides can only be transported out of hepatocytes if apolipoprotein converts them to lipoproteins ([Fig. 1-44](#)). Alterations in one or more of these biochemical processes can result in the accumulation of triglycerides and other lipid metabolites, resulting in hepatic lipidosis.

39

40

**Fig. 1-44 Fatty liver.** Schematic diagram of the possible mechanisms leading to the accumulation of triglycerides in a fatty liver. Defects in any of the steps of uptake, catabolism, or secretion can result in lipid accumulation in the cell. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

In domestic animals, hepatic lipidosis most commonly arises from conditions that cause increased mobilization of body fat stores. Such conditions usually occur when there is increased demand for energy over a short duration, as in late pregnancy and early lactation in dairy cows (pregnancy toxemia and ketosis, respectively). Hepatic lipidosis is also observed with nutritional disorders including obesity (increased transport of dietary lipids or mobilization from adipose tissue), protein-calorie malnutrition (impaired apolipoprotein synthesis), and starvation (increased mobilization of triglycerides), but it also occurs in genetically inherited disorders, such as glycogen storage (Niemann-Pick disease [phospholipid sphingomyelin]) and Wilson's disease, and in endocrine disease, such as diabetes mellitus (increased mobilization of triglycerides). Certain chemical agents, such as  $\text{CCl}_4$  (carbon tetrachloride is used in industrial applications) and yellow phosphorus (used in manufacturing other products) for example (rarely seen in clinical medical practice today), can also induce hepatic lipidosis via decreased oxidation of free fatty acids. In some disorders, such as feline hepatic lipidosis (feline fatty liver syndrome) and fat cow syndrome, the cause of hepatic lipidosis is unclear.

Grossly, mild fatty change may not be detectable, but livers with notable lipidosis are enlarged, yellow, soft and friable, and the edges of the lobes are rounded and broad instead of sharp and flat (Fig. 1-45, A). When incised, the cut surface of severely affected livers can bulge and the hepatic parenchyma is soft and friable and has a greasy texture attributable to lipid within hepatocytes. In addition, a 1-cm-thick transverse section from a liver lobe may float in formalin, again indicative of lipid within hepatocytes.

It is important to distinguish these gross lesions from the lesions present in glucocorticoid (steroid) hepatopathy in dogs. The liver in glucocorticoid hepatopathy is also enlarged and has rounded edges, but it is pale beige to tan-white, firm, and nongreasy (Fig. 1-46, A). Cut sections do not float in formalin. These gross lesions are attributable to the accumulation of glycogen and water in the cytoplasm of hepatocytes (see Chapter 8).

## Pathologic Basis of Veterinary Disease, 4th Edition

Microscopically, hepatocytes with lipidosis are vacuolated, with the extent of the vacuolation depending on the severity of the lipidosis. Initially there are a few small clear vacuoles that increase in size and number and eventually coalesce into larger vacuoles. These vacuoles have sharply delineated borders (Fig. 1-45, *B*), which are attributed to the hydrophobic interface between water and lipid in the cell's cytoplasm and should be compared with vacuoles that result from glycogen accumulation (Fig. 1-46, *B*). In hepatocytes with large amounts of fat, the nucleus can be displaced to the periphery, and the cell can resemble an adipocyte. In extremely affected livers in which all of the hepatocytes are filled with lipid, the liver can resemble fat and can be identifiable only by the presence of portal areas.

40

41

**Fig. 1-45 Steatosis (fatty liver, fatty change, hepatic lipidosis), liver, ox.**

**A**, Note the uniformly pale yellow surface. The liver is usually enlarged and the edges rounded. The cut surface bulges on incision and may feel greasy. **B**, In this severely affected liver, all hepatocytes are vacuolated and their nuclei have been displaced to the side. H&E stain. (*A and B*, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Vacuoles in hepatocytes may be due to fat accumulation but can also occur as the result of intracellular accumulation of glycogen or water. Fat is confirmed by special stains, but as alcohol and clearing agents used during the processing of paraffin-embedded sections dissolve fat, formalin-fixed frozen sections—properly stained for fat—must be used to confirm the presence of fat in hepatocytes. Fat stains, which are alcoholic solutions of fat soluble dyes, include Sudan III, Scharlach R, and Oil-Red-O. Glycogen is confirmed by the PAS and PAS-diastrase reactions described later (see Glycogen). Vacuoles that do not stain with either fat or PAS are presumed to be a result of the accumulation of water (hydropic degeneration).

**Fig. 1-46 Glucocorticoid hepatopathy, liver, dog.** **A**, Extensive accumulation of glycogen in hepatocytes leads to an enlarged and pale brown to beige liver in dogs with glucocorticoid excess from endogenous (Cushing's disease) or exogenous sources. The liver is usually enlarged and the edges rounded. This cut surface would bulge on incision and not be greasy. **B**, Note the swollen hepatocytes (arrows) with extensive cytoplasmic vacuolation. H&E stain. (**A**, Courtesy Dr. K. Bailey, College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. J. M. Cullen, College of Veterinary Medicine, North Carolina State University.)

41

### 1.10.1.2 FATTY INFILTRATION

42

Fatty infiltration should not be confused with fatty change or steatosis, in which the lipid is intracellular (see previous discussion). Adipocytes are normally present in connective tissue and in limited numbers between fasciculi of skeletal muscle and subepicardially between cardiac myocytes. When increased lipid is to be stored, adipocytes increase in number, and the process is called fatty infiltration. It occurs in old age and in obesity in which there is hyperplasia of adipocytes by means of proliferation of preadipocytes. When myocytes of skeletal muscle atrophy and disappear, the lost myocytes may be replaced by adipocytes (see [Fig. 15-29](#)).

### 1.10.2 GLYCOGEN

Variable amounts of glycogen are normally stored in hepatocytes and myocytes (the amount in the liver depends on the interval between sampling and the last meal). Hepatocytes of starved animals are usually devoid of glycogen. Excessive amounts of glycogen are present in animals in which glucose or glycogen metabolism is abnormal, such as diabetes mellitus, or in animals that have received excess amounts of corticosteroids. Large amounts of glycogen can be found in the livers of young growing animals and in animals that are well nourished and on diets of commercially produced feeds.

In diabetes, glycogen is found not only in hepatocytes but also in the epithelial cells of renal proximal tubules and in B cells of the Islets of Langerhans. Hepatocytes are highly permeable to glucose, and hyperglycemia leads to increased glycogen concentration in these cells. Also in diabetes, large amounts of glucose are passed out in

## Pathologic Basis of Veterinary Disease, 4th Edition

the glomerular filtrate and exceed the resorptive capacity of the renal tubule epithelial cells. These cells, when overloaded with glucose, convert it into glycogen, which accumulates intracellularly.

Grossly, physiologic deposits of glycogen cannot be detected, but in steroid-induced hepatopathy, where massive amounts of glycogen are stored, the liver may be enlarged and pale ([Fig. 1-46](#)).

Microscopically the amount of glycogen demonstrated in hepatocytes is chiefly a function of the original concentration in the cell, the delay between death and fixation during which time the glycogen is metabolized, and the type of fixation. Despite frequent statements that glycogen is best preserved by fixing tissue in an alcoholic fixative (e.g., absolute alcohol or 10% formalin in absolute alcohol), glycogen can be well preserved by fixation in an ordinary 10% buffered neutral formalin solution at 4°C in a refrigerator during the period of fixation ([Fig. 1-47, A](#)). This procedure retains most of the glycogen but avoids the excessive shrinkage and distortion of tissues attributed to fixation in alcoholic fixatives and also avoids “polarization,” the phenomenon whereby the glycogen is displaced to the side of the cell away from the surface. Polarization is seen in fixation at room temperature but is worst with alcoholic fixatives ([Fig. 1-47, B](#)).

**Fig. 1-47 Glycogen, liver, dog.** **A**, Ten-percent buffered neutral formalin fixation at 4° C. Glycogen (purplish-red) is uniformly dispersed throughout the cytoplasm of all hepatocytes. Periodic acid–Schiff technique. **B**, Absolute alcohol (ethanol) fixation at room temperature. The glycogen in each hepatocyte has been pushed to the side of the cell, so-called polarization of glycogen. Periodic acid–Schiff technique. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Histologically, glycogen is demonstrated specifically by the PAS reaction using two serial tissue sections mounted on glass slides. The tissue section on the first slide is pretreated with diastase, which digests the glycogen in the tissue, and the tissue section on the second glass slide is untreated. Thus the deposits digested by diastase are glycogen. The PAS reaction breaks 1,2-glycol linkages to form aldehydes, which are revealed by Schiff's reagent. These linkages occur in substances other than glycogen, hence the use of two slides including one pretreated with diastase to specifically identify glycogen. Microscopically, glycogen appears as clear

## Pathologic Basis of Veterinary Disease, 4th Edition

vacuoles in the cytoplasm of the cell. In contrast to intracellular fat whose vacuoles are rounded and sharply delineated, glycogen forms irregular clear spaces with indistinct outlines. Usually the nucleus remains centrally located in the hepatocyte. However, if very large amounts of glycogen are stored in hepatocytes, as in steroid-induced hepatopathy, hepatocyte nuclei may be displaced peripherally.

In glycogen storage diseases (glycogenoses), glycogen accumulates, sometimes in massive amounts in cells as a result of a defective enzyme. Exactly which cells store glycogen depends on the defective enzyme, but skeletal muscle is frequently involved (see [Chapters 14](#) and [15](#) for more detail).

42

### 1.10.3 PROTEINS

43

In histologic sections, intracellular protein accumulations are of several types and include rounded eosinophilic droplets, vacuoles, and aggregates in cells. The causes of these accumulations vary widely.

#### 1.10.3.1 HYALINE CHANGE

The adjective “hyaline” is defined by *Dorland’s Medical Dictionary* as “glassy and transparent or nearly so,” and the noun “hyalin” as a “translucent albuminoid substance.” However, histologically the term has come to mean having a homogeneous, eosinophilic, and glassy (translucent) appearance. Some pathologists also add “amorphous,” and the lesion has been termed both a change and a degeneration, but the term hyaline is purely descriptive and is rather loosely applied to a variety of changes, none of which is a true cellular degeneration. Hyaline substances may be intracellular or extracellular.

##### 1.10.3.1.1 Intracellular Hyaline Proteins

Intracellular hyaline proteins include resorption droplets, Russell bodies in plasma cells, and those caused by defects in protein folding.

##### 1.10.3.1.1.1 Resorption droplets in the epithelial cells of renal proximal tubules

There is normally very little protein in the filtrate from the glomerulus, and what is present is resorbed by the proximal tubule epithelial cells. When the protein concentration of the filtrate is high, as in a proteinuria, for example from glomerular damage, this protein is taken up by the proximal tubule epithelial cells into vesicles where, in H&E stained sections, they appear as hyaline droplets in the cytoplasm ([Fig. 1-48, A](#)). The vesicles fuse with the lysosomes to form phagolysosomes, where the protein is metabolized. If the proteinuria ceases, the formation of hyaline droplets also ceases. This condition was once called “hyaline droplet degeneration.” It is not a degeneration but an exaggeration of a normal process. Also, similar droplets are seen in the intestinal epithelium of neonatal pigs and calves that have recently ingested colostrum.

##### 1.10.3.1.1.2 Excessive production of normal protein

Hyaline bodies called Russell bodies are seen in the cytoplasm of some plasma cells (Mott cells). These bodies are large, eosinophilic, homogenous, and amorphous and consist of immunoglobulin ( $\gamma$ -globulin). Russell bodies have been described as “manifestations of cellular indigestion” in the ER.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

1.10.3.1.1.3

### Defects in protein folding

During protein synthesis on ribosomes, proper folding of the protein is essential for its transport in the cell's organelles. Normally, if there is a defect in folding, the protein is eliminated by the proteasome complex. On occasion, these folded proteins accumulate in cells as is seen in some of the human neurodegenerative diseases, including Alzheimer's disease. Sometimes folded proteins may accumulate in tissue, and some types of amyloidosis are examples of this process.

1.10.4

### OTHER INTRACELLULAR INCLUSIONS

1.10.4.1

#### AUTOPHAGIC VACUOLES

Autophagic vacuoles are large eosinophilic intracytoplasmic inclusions, which ultrastructurally are autophagosomes (Fig. 1-35). They are a common response to injury in cells with sublethal damage, particularly hepatocytes, and are a mechanism by which the cell rids itself of damaged or senescent organelles. A portion of the cell membrane invaginates and envelops the affected organelles to form an autophagosome, which then fuses with a lysosome to cause degradation of the contents. Digestion of the material in autophagic vacuoles may leave some lamellar debris, and this debris may either be exocytosed from the cell or remain intracellularly to form lipofuscin (see later discussion of pigments).

1.10.4.2

#### CRYSTALLINE PROTEIN INCLUSION BODIES

Crystalline protein inclusions, sometimes known as crystalloids, occur in normal hepatocytes and renal tubular epithelial cells, particularly in old dogs. They are large, eosinophilic, and rhomboidal and may be so large as to distort the nucleus or the cell (Fig. 1-48, B). Except for being age related, they are of unknown significance. In fact, an increased incidence of these inclusions is the most consistent age-related change in canine hepatocytes.

1.10.4.3

#### VIRAL INCLUSION BODIES

Infection of host cells by some types of viruses results in the formation of characteristic inclusion bodies, which may be intranuclear, intracytoplasmic, or both. They are accumulations of viral protein and are useful diagnostically to confirm a specific viral disease.

DNA viruses such as herpesviruses, adenoviruses, and parvoviruses tend to produce only intranuclear inclusions. These inclusions are round to oval and can be eosinophilic (herpesviruses), basophilic, or amphophilic (adenoviruses). Pox viruses are also DNA viruses, but they produce large distinct eosinophilic intracytoplasmic inclusion bodies in infected cells.

A few RNA viruses produce intracytoplasmic inclusions. Examples are the distinctive cytoplasmic neuronal inclusions of rabies (Negri bodies) and the epithelial inclusions of canine distemper. Distemper causes both intranuclear and intracytoplasmic inclusions in nervous tissue (Fig. 1-48, C). Viral inclusions are usually surrounded by a clear halo, particularly in the nucleus. Cells with inclusion bodies and adjacent cells usually have signs of degeneration or cell death. Many of these viral inclusion bodies will be discussed in the systemic pathology chapters of this book.

43

44

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 1.10.4.4 LEAD INCLUSION BODIES

In lead poisoning, irregularly shaped intranuclear inclusion bodies that are acid-fast may be present in renal tubular epithelial cells ([Fig. 1-48, D](#)). They contain both lead and protein. When they are present, they are helpful in the diagnosis of lead poisoning. In dogs, they must be distinguished from the protein crystalline protein inclusions described previously.

\* Portions of this section are from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

### 1.11 EXTRACELLULAR ACCUMULATIONS

#### 1.11.1 HYALINE SUBSTANCES

Extracellular hyaline substances include the following:

1. Hyaline casts in the lumens of renal tubules in a proteinuria
2. Serum or plasma in blood vessels
3. Plasma proteins in vessel walls (e.g., in porcine edema disease). These substances are subendothelial hyaline deposits, primarily seen in arterioles of the brain stem in pigs with porcine edema disease ([Fig. 1-51](#)).
4. Old scars. With age, the number of nuclei in collagen deposits decrease as the result of cell senescence, and the collagen fibers condense and become hyalinized.
5. Thickened basement membranes (e.g., in glomerulonephritis and in the capillaries of the choroid plexus with old age)
6. Hyaline membranes of the alveolar walls (see [Chapter 9](#))
7. Hyaline microthrombi (e.g., platelet microthrombi) in disseminated intravascular coagulation (DIC); often visible in glomerular capillaries and pulmonary alveolar capillaries
8. Amyloid as described next

#### 1.11.1.1 AMYLOID

The name *amyloid* is given to a chemically diverse group of chiefly extracellular proteinaceous substances that appear histologically and ultrastructurally similar. The name means “starchlike” and was applied to these proteins because when the surface of an affected organ was treated with an iodine solution and then with dilute sulfuric acid, it turned blue, a positive test for starch ([Fig. 1-49](#)).

Histologically, amyloid is an eosinophilic amorphous hyaline substance ([Fig. 1-50, A](#)). It is extracellular and compresses adjacent parenchymal cells, causing atrophy or death from compression and/or ischemia. This outcome is most evident in hepatic amyloidosis, in which the protein is deposited in the space of Disse. Here it

## Pathologic Basis of Veterinary Disease, 4th Edition

---

compresses the adjacent hepatocytes and interferes with the hepatocytes' access to blood and nutrients in the sinusoids.

The most frequently used special stain for amyloid is Congo red. It stains amyloid orange to orange red (Fig. 1-50, *B*) and under polarized light imparts a light green, so-called apple green fluorescence (see Chapter 11). Congo red staining is not absolutely specific, and transmission electron microscopy to identify 7.5- to 10-nm filaments may be necessary.

Chemically, amyloid is not one substance. It is a diverse group of glycoproteins whose protein component is configured in a  $\beta$ -pleated sheet pattern, which is responsible for the characteristic staining with Congo red. In human beings, there are three major and several minor forms. In animals, there are two major and two minor forms, which are chemically different but histologically similar.

AL amyloid consists of immunoglobulin light chains, is monoclonal, and is secreted by plasma cells in immunocyte dyscrasias (B-lymphocyte proliferative disorders). AA amyloid is not an immunoglobulin but is synthesized from a precursor protein SAA (serum amyloid associated) secreted by the liver. SAA concentration is increased in inflammatory states, but this increase does not necessarily lead to amyloid deposition in all cases in response to IL-1 and IL-6. A minor form of amyloidosis is hereditary amyloidosis found in Shar-Pei dogs and in Abyssinian cats.

45

46

**Fig. 1-49 Amyloidosis, kidney, cross section, dog.** Note the blue-black foci, which are glomeruli-containing amyloid stained by Lugol's iodine.  
(Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 1-50 Amyloidosis, kidney, dog.** **A**, The renal glomerulus contains large amounts of pale homogeneous eosinophilic material, which is amyloid. H&E stain. **B**, The amyloid in the glomeruli stains orange. Congo red stain. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

$\beta$ -Amyloid found in Alzheimer's disease in human beings has been detected in the brains of aged dogs.

### 1.11.1.1.1

#### Classification of Amyloidosis

Amyloidosis has been classified in several ways (i.e., primary versus secondary, systemic [generalized] versus localized, and a combination of these categories). Systemic amyloidosis (generalized) is also divided into primary amyloidosis (immunocyte dyscrasia) and secondary amyloidosis (reactive systemic amyloidosis).

- Immunocyte dyscrasia is the most common form of amyloidosis in human beings, but not in animals. The amyloid consists of amyloid light chains and is indicative of a plasma cell dyscrasia. These cells also secrete large amounts of  $\lambda$ - and  $\kappa$ -light chains into blood and urine (Bence Jones proteins), which are diagnostically important.
- Reactive systemic amyloidosis was initially called secondary amyloidosis because it was secondary to chronic inflammatory conditions, particularly those causing a chronic antigenic stimulation with protracted breakdown of cells. It is the most common form of amyloidosis in animals, and the amyloid is deposited in kidney, liver, spleen, and lymph nodes. Functionally, and most often in old dogs, amyloid deposits in the kidney are the most important because they are located in the mesangium and basement membranes of renal glomeruli and cause a proteinuria. The spleen is the most frequent site in reactive systemic amyloidosis, and amyloid is deposited in the periarteriolar lymphoid sheaths and red pulp. The space of Disse of the liver is the usual site for amyloidosis in birds.
- Localized amyloidosis involves a single organ or tissue. Such localized lesions are in the nasal vestibule or rostral portion of the nasal septum and turbinates in horses and in the pancreatic islets in cats.

## Pathologic Basis of Veterinary Disease, 4th Edition

- $\beta$ -Amyloidosis. Extracellular accumulation of amyloid- $\beta$  protein (A $\beta$ ) is characteristic of Alzheimer's disease in humans. This type of amyloid has also been identified in the brains of aged dogs, the highest concentration being in the frontal cortex. Dogs older than 13 years had A $\beta$  plaques.

### 1.11.1.1.2 Location of Amyloid Deposits in Animals

The kidney (glomeruli in most animals and medullae in cats), liver (space of Disse in cattle, horses, dogs, and cats), and spleen (germinal centers) are common sites. Other organs affected include the stomach, intestine (lamina propria), thyroid (C-cell tumor), skin (dermis and subcutis of horses), lymph node (germinal centers), adrenal cortex, pancreas (islets of Langerhans in cats), nasal septum and turbinates (walls of submucosal vessels and basement membranes of mucosal glands of horses), and meningeal and cerebral vessels of older dogs. See the appropriate organ chapters for more detail.

### 1.11.2 OTHER EXTRACELLULAR ACCUMULATIONS

#### 1.11.2.1 FIBRINOID CHANGE

Fibrinoid change, also known as the fibrinoid necrosis and fibrinoid degeneration, is a term applied to a pattern of lesions most often observed in the vascular system. The terms *fibrinoid degeneration* and *necrosis* are inappropriate, as the process is not a true regressive alteration of cells. Rather, fibrinoid change is the result of the deposition of immunoglobulin, complement, and/or plasma proteins, including fibrin in the wall of a vessel. This lesion is due to injury to the intima and media such as occurs in the immune-mediated vasculitides.

Grossly, fibrinoid change cannot be observed; however, it is often accompanied by thrombosis and hemorrhage, and when these two lesions are present in a vascular pattern of distribution, fibrinoid change of the vasculature should be considered. Microscopically, direct injury to endothelial cells, basement membrane, or myocytes, such as caused by viruses or toxins, or indirect injury, such as caused by activation complement proteins, can lead to activation of the acute inflammatory cascade and the deposition of plasma proteins in the vessel walls. These proteins, especially fibrin, stain intensely red (eosinophilic) with H&E stains, and involve the vessel wall circumferentially to varying depths of the tunica intima and tunica media (Fig. 1-51). This lesion is also often accompanied by cellular and nuclear debris from injured vascular cells and inflammatory cells. These proteins contribute to the vascular "eosinophilia," which has been described somewhat differently by different pathologists. There is general agreement that the material is eosinophilic, which is sometimes described as "smudgy" or "deeply eosinophilic." Some pathologists add "homogeneous" and others "amorphous" to the descriptive terminology of fibrinoid change.

#### 1.11.2.2 GOUT

Gout is the deposition of sodium urate crystals or urates in tissue. It occurs in human beings, birds, and reptiles but has not been reported in domestic animals.

In the most common form in human beings, urate crystals are deposited in the articular and periarticular tissues and elicit an acute inflammatory response characterized by the presence of neutrophils and macrophages and large aggregations of urate crystals called tophi. These tophi may be visible grossly and are pathognomonic of gout. Later in the course of the disease, the inflammation becomes chronic and a foreign body reaction to the tophi develops. Microscopically, urate crystals are acicular and birefringent and they, or

46

47

## Pathologic Basis of Veterinary Disease, 4th Edition

the spaces left after they have been dissolved during the preparation of paraffin-embedded histological sections, are visibly surrounded by numerous neutrophils, macrophages, and giant cells.

**Fig. 1-51 Fibrinoid change, artery.** Note the deeply eosinophilic circumferential band in the tunica media. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

In birds and reptiles, there are two forms including: (1) the articular type, which is rare; and (2) a visceral type. The latter characteristically affects the visceral serosae, particularly parietal pericardium, and the kidneys. The serosa is covered with a thin layer of gray granules, and the gross appearance is diagnostic. In the renal form, urate deposits are visible in renal tubules and ureters. Uric acid and urates are the end products of purine metabolism, and in birds and reptiles these products are eliminated as semisolid urates. Visceral gout is usually diagnosed only at necropsy and is seen sporadically due to vitamin A deficiency, high-protein diets, and renal injury.

1.11.2.3

### PSEUDOGOUT

Pseudogout is characterized by deposits of calcium pyrophosphate crystals. It is well recognized in human beings but has been reported in the dog, in which it is rare. The pathogenesis of the canine disease is unknown, but in human beings one form is inherited as an autosomal dominant trait. Grossly, there are chalky white deposits in the joints, which histologically show a chronic reaction with aggregates of crystalline material, macrophages, and fibrosis. The disease may be differentiated from gout by the chemical analysis of the crystalline deposits.

1.11.2.4

### CHOLESTEROL

Cholesterol crystals are the by-products of hemorrhage and necrosis. They are dissolved out of the tissue specimen during the preparation of paraffin-embedded sections, leaving characteristic clefts which, in section, resemble shards of glass. Actually the crystals are thin rhomboidal plates with one corner notched out, their outline resembling that of the state of Utah. Cholesterol crystals in tissue have no significance except that they

## Pathologic Basis of Veterinary Disease, 4th Edition

indicate the site of an old hemorrhage or tissue necrosis, and they may be present in atheromas (i.e., mass of degenerated, thickened arterial intima occurring in atherosclerosis). However, in the choroid plexus of the lateral ventricles of old horses, cholesterol crystals can induce a granulomatous response, and the resultant cholesterol granuloma or cholesteatoma can become so large as to obstruct the outflow of cerebrospinal fluid through the interventricular foramen (foramen of Munro), resulting in obstructive hydrocephalus. It is thought that these granulomas are secondary to cholesterol crystals from hemorrhages into the choroid plexus. Grossly, the cholesterol appears as firm, crumbly gray nodules in the cholesteatomas.

### 1.12 PATHOLOGIC CALCIFICATION\*

Calcium salts, usually in the form of phosphates or carbonates, may be deposited in dead, dying, or normal tissue. This process is known as pathologic calcification and occurs in two forms: dystrophic and metastatic. When the deposition occurs locally in dying tissue, it is known as dystrophic calcification; it occurs despite normal serum concentrations of calcium and in the absence of derangements in calcium metabolism. In contrast, the deposition of calcium salts in otherwise normal tissue is known as metastatic calcification, and it almost always results from hypercalcemia secondary to some disturbance in calcium metabolism.

#### 1.12.1 DYSTROPHIC CALCIFICATION

Dystrophic calcification occurs in areas of necrosis, no matter the type of necrosis-coagulative, caseous, liquefactive, or fat necrosis, but is minimal in liquefactive necrosis. Dead and dying cells can no longer regulate the influx of calcium into their cytosol, and calcium accumulates in the mitochondria.

Common sites include necrotic myocardium (Fig. 1-52), necrotic skeletal muscle, granulomas such as tuberculoid granulomas in cattle, and dead parasites, such as hydatid cysts in cattle and trichinae in pigs. Calcium deposits are relatively permanent but harmless unless they interfere mechanically (e.g., the movement of a calcified heart valve). Their significance is that they are an indicator of previous injury to a tissue.

Calcification in or under the skin has been designated calcinosis. There are two main forms: (1) calcinosis cutis and (2) calcinosis circumscripta (also see Chapter 17). Calcinosis cutis occurs in dogs with hyperadrenocorticism from either endogenous or exogenous glucocorticoids and has been regarded as idiopathic calcification by some pathologists and dystrophic calcification by others. There is mineralization of the dermal collagen, and epidermal and follicular basement membranes. Calcinosis circumscripta is considered to be dystrophic. It has a preference for German shepherds and Great Danes, in which it is familial. Also, it has been associated with repetitive trauma and at the site of buried sutures of polydioxanone.

Grossly the affected areas of tissue are white and when incised have a gritty feel to them (Fig. 1-52). Microscopically, calcium salts stain blue with hematoxylin and appear as fine amorphous granules or clumps, which can be either intracellular or extracellular. However, the full extent of the calcification may not be evident in H&E stained sections (Fig. 1-53, A) but is revealed more dramatically by special stains, such as von Kossa and Alizarin red S (Fig. 1-53, B). The von Kossa method is not specific for calcium but stains phosphates and carbonates. These substances are almost always complexed with calcium.

\* Portions of this section are from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 1.12.2 METASTATIC CALCIFICATION

Metastatic calcification occurs in normal tissue and is secondary to hypercalcemia. The basic abnormality is the entry of large amounts of calcium ions into cells. These ions precipitate on organelles, particularly mitochondria.

The four causes of metastatic calcification in order of their importance in veterinary medicine are as follows:

1. Renal failure. Renal failure results in retention of phosphates, which induce a secondary renal hyperparathyroidism and hypercalcemia. Calcium is deposited in the gastric mucosa, kidney, and alveolar septa. 48
2. Vitamin D toxicosis. The ingestion of calcinogenic plants, such as *Cestrum diurnum* by herbivores, results in severe soft tissue mineralization, chiefly involving the aorta, heart, and lungs. In the heart, the endocardium of the right and left atria and left ventricle is often strikingly mineralized. Acute vitamin D toxicosis in dogs and cats is commonly caused by ingestion of rodenticides containing cholecalciferol. Intestinal mucosa, vessel walls, lung, and kidneys are mineralized. 49
3. Parathormone (PTH) and PTH-related protein. Primary hyperparathyroidism is rare. Hypercalcemia and elevated concentrations of PTH-related protein can be associated with canine malignant lymphomas and canine adenocarcinoma of the apocrine glands of the anal sac. Intestinal mucosa, vessel walls, lung, and kidneys are mineralized.
4. Destruction of bone from primary or metastatic neoplasms.

**Fig. 1-52 Calcification, vitamin E/selenium deficiency, myodegeneration, heart, lamb.** The multiple white lesions are areas of necrosis of cardiac myocytes that have been calcified. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

H&E stain. **B**, The calcium is stained black. von Kossa stain. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 1.13 HETEROTOPIC BONE (ECTOPIC BONE)

Some lesions of dystrophic and metastatic calcification may be confused on gross examination with ectopic ossification, the name given to the process of production of bone at an abnormal site. Ectopic bone is of two types: heterotopic or osseous metaplasia. “Heterotopia” refers to foci of cells or tissues, which are microscopically normal but present at an abnormal location. They are considered to arise from embryonic cell rests. The other type of bone is formed by osseous metaplasia, usually from another type of connective tissue. Fibroblasts differentiate into osteoblasts that form osteoid, which is calcified as in normal bone (Fig. 1-54). This is the more common type.

Fig. 1-54 **Ectopic bone, lung, dog.** A nodule of mature bone in the connective tissue of the lung. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Heterotopic bone is found at many sites, commonly as spicules or nodules of bone in connective tissue of lungs of dogs and cattle, and in the canine dura mater (dural ossification or ossifying pachymeningitis) and at sites of dystrophic and metastatic calcification.

### 1.14 PIGMENTS

It is customary in pathology textbooks to group substances that impart an unusual color to the body (systemic) or its tissues (localized), under the category of pigments. Many of these pigments are unrelated in their origin, but their importance lies in the fact that the clinician and the pathologist need to be able to recognize them grossly, and the pathologist also needs to be able to identify them histologically. Recognition may provide valuable clues in understanding the disease process at hand and its underlying pathogenesis. Because of their diversity, pigments are usually classified broadly into two groups: exogenous (formed outside the body) and endogenous (formed inside the body).

#### 1.14.1 EXOGENOUS PIGMENTS

These pigments include carbon, tattoos, dusts, carotenoids, and tetracycline.

##### 1.14.1.1 CARBON

Carbon is the most common exogenous pigment. The usual route of entry into the body is via inhalation, and its accumulation in the lung results in a condition called anthracosis (also known as black lung).

Carbon is ubiquitous in the air and all animals are exposed, but those most likely to show gross lesions live in an environment with substantial air pollution, such as adjacent to busy highways (e.g., animals in a zoo near a highway or animals living in a house with a smoker). In the alveoli, the carbon is phagocytosed by macrophages, which transport it via the lymphatics to the regional tracheobronchial lymph nodes. Because elemental carbon is inert and not metabolized by the body, it remains in the tissue for the life of the animal.

Grossly the lungs are usually speckled with fine 1- to 2-mm-diameter subpleural black foci, which are most visible if the lungs are exsanguinated ([Fig. 1-55, A](#)). In severely affected cases, the medulla of the tracheobronchial lymph nodes may be black. The heavy deposits are in this location because of the concentration of sinus histiocytes (macrophages) in the medulla.

Microscopically, carbon presents as fine black granules and may be extracellular or intracellular (within macrophages). Carbon pigment may be within the alveolar walls or be frequently present as black peribronchiolar or peribronchial foci ([Fig. 1-55, B](#)). Because of the nonreactiveness of carbon, there are no histochemical tests for it. Unlike many other pigments, it is resistant to solvents and bleaching agents.

49

50

Fig. 1-55 **Anthracosis, lung, aged dog.** **A**, The fine black foci are peribronchiolar deposits of carbon. The animal was exsanguinated at euthanasia to remove the blood from the lung to render the carbon deposits more visible. **B**, Carbon (*black*) inhaled into the alveoli has been phagocytosed by macrophages and transported to the peribronchial region. H&E stain. (*A and B*, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 1.14.1.2 TATTOOS

Animals are frequently tattooed as a method of identification. These pigments, which include carbon, are introduced into the dermis. Some of the pigments are phagocytosed by macrophages, whereas the remainder remains free in the dermis where it can remain indefinitely and does not invoke any inflammatory reaction.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 1.14.1.3 DUSTS

Pneumoconiosis is the general term used for any dust inhaled into and retained in the lung. Anthracosis, from the inhalation of carbon, is a subtype of pneumoconiosis. Inhalation of silicon (e.g., from quarries) is called silicosis. These minute particles enter the lungs by escaping the mucociliary defense mechanisms of the nasal and upper respiratory systems (see [Chapter 9](#)) and are deposited in pulmonary alveoli where they may be phagocytosed and carried to the peribronchial regions. Some types of silica evoke a fibrous reaction, which may ultimately form nodules. Microscopically the mineral is visible as birefringent crystals under polarized light.

**Fig. 1-56 Carotenosis, kidney and the perirenal fat, Jersey ox.**

Accumulation of carotenoids in the adipocytes has colored the fat yellow to dark yellow. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 1.14.1.4 CAROTENOID PIGMENTS

These pigments are also called lipochrome pigments, although this term is sometimes confused with lipofuscin (see later discussion). They are fat-soluble pigments of plant origin and include the precursors of vitamin A, namely  $\beta$ -carotene.

Grossly, these pigments normally occur in a wide variety of tissue, such as adrenal cortical cells, corpus luteum-lutein cells, Kupffer cells, and testicular cells, and in the plasma/serum and fat of horses and Jersey and Guernsey cattle and sometimes dogs ([Fig. 1-56](#)). Carotenoids discolor fat yellow to orange-yellow. The concentration of carotenoids retained in tissue depends upon the species of animal. Some animals store little or no carotenoids and have white fat and clear serum. These animals include Holstein cattle, sheep, goats, and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cats. As fat stores are depleted (e.g., in starvation or cachexia), carotenoids become concentrated in the adipocytes, giving them a dark yellowish-brown color.

Microscopically, carotenoids are not seen in routine formalin-fixed paraffin-embedded sections because the alcohols and clearing agents remove the fat-soluble pigments.

The significance of carotenoids is that they may obscure or confuse the detection of icterus. In those animals whose fat and serum are devoid of carotenoids, a yellow discoloration is easily detected and is most likely to be caused by bilirubin (i.e., icterus).

50

51

### 1.14.1.5 TETRACYCLINE

Tetracycline-based antibiotics administered during the development of teeth will be deposited in mineralizing dentin, enamel, and cementum, staining the teeth or portions of them yellow or brown (Fig. 1-57). Thus tetracycline administered to a pregnant animal stains the deciduous teeth of the offspring. Tetracycline also stains bone that is being laid down and has been used experimentally as a marker for that bone.

### 1.14.2 ENDOGENOUS PIGMENTS

#### 1.14.2.1 MELANIN

Melanin is the pigment normally present in the epidermis and is responsible for the color of the skin and hair. It is also normally present in the retina, iris, and in small amounts in the pia-arachnoid of black animals (e.g., Suffolk sheep [Fig. 1-58]) and in the oral mucous membrane of some breeds (e.g., Jersey cows and Chow dogs).

Melanin is secreted by cells called melanocytes. In the skin of animals, these cells are in the basal layer and transfer their pigment by means of dendritic processes to adjacent keratinocytes, where the melanin is often arranged as a cap over the nucleus to provide some protection from ultraviolet radiation. Melanin is formed by the oxidation of tyrosine, which requires the copper-containing enzyme tyrosinase. Thus in copper deficiency, particularly in cattle and sheep, there is a fading of the coat color, and this is most obvious in black wool. A general lack of melanin can be due to a metabolic defect: a lack of tyrosinase. This condition is called albinism, and the affected animal is called an albino. Histologically the melanocytes appear normal.

**Fig. 1-57 Tetracycline staining, teeth, young dog.** The teeth of this dog have been stained yellow by the tetracycline ingested during their development. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Pathologically, melanin is present in hyperpigmentation of the skin associated with many types of chronic injury and endocrinopathies such as hyperadrenalism and in primary neoplasms of melanocytes (melanomas and melanosarcomas), although highly malignant tumors may have little or no pigment.

Microscopically, melanin is stored in melanosomes in the cytoplasm of melanocytes. However, if there is damage to the cells containing melanin (e.g., damage to melanocytes and basal cells of the skin), the free melanin is phagocytosed by macrophages, which are termed melanophages.

Extensive deposits of congenital melanin in tissues is termed congenital melanosis. It occurs in the lungs and aorta (intima) of cattle, sheep, and pigs as brown to black spots up to a couple of centimeters in diameter ([Fig. 1-59](#)). Melanosis of the lung is visible both subpleurally and in cross sections of the parenchyma. These deposits of melanin have no adverse effect, but organs with extensive melanosis may be aesthetically unacceptable as food and thus will be condemned at the packing plant.

**Fig. 1-58 Congenital melanosis, leptomeninges, Suffolk sheep.** The leptomeninges have scattered black areas of melanin. This is normal in black-faced sheep. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

51

### 1.14.2.2 LIPOFUSCIN-CEROID

52

Lipofuscin, known as “wear-and-tear” pigment, has in the past been described as accumulating with age and in certain pathologic conditions. However, in recent years, lipofuscin, now referred to as “age pigment,” has been differentiated from a pathologically accumulating similar pigment called ceroid, described later.

Lipofuscin accumulates in a time-dependent manner in postmitotic cells (neurons, cardiac myocytes [Fig. 1-60, A], and skeletal muscle myocytes) and in slowly dividing cells, such as hepatocytes and glial cells, and this process is present at a few months of age. Lipofuscin is also found in other cells, but as these replicate, the lipofuscin is divided between the daughter cells and thus does not accumulate to the same extent as it does in postmitotic cells. Lipofuscin is the end result of autophagocytosis of cell constituents, such as organelles, and is the final undegradable remnant of that process. As the pigment cannot be removed by further lysosomal degradation or exocytosis, it accumulates in lysosomes, a form of biologic garbage (Fig. 1-60, B).

Fig. 1-59 **Congenital melanosis, lung, pig.** Melanin deposits are subpleural and extend into the substance of a lung. The lesion has no pathological significance. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 1-60 **Lipofuscinosis, heart, human.** **A**, Note the brown lipofuscin granules (*arrows*) at the poles of the myocyte nuclei. H&E stain. **B**, Lipofuscin (*black*) is perinuclear and within lysosomes. TEM. Uranyl acetate and lead citrate stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

Ceroid has many of the same histochemical features as lipofuscin (see later discussion) but is found in response to severe malnutrition, including vitamin E deficiency, cachexia from cancer, irradiation, and in the inherited disease neuronal ceroid-lipofuscinosis. It accumulates in Kupffer cells and to a lesser extent in hepatocytes, skeletal and smooth muscle myocytes, and in inherited neuronal ceroid-lipofuscinosis, where it accumulates in neurons. It can be either intracellular or extracellular. Unlike lipofuscin, it is considered to have a deleterious effect on the cell.

Both lipofuscin and ceroid have many common histologic and histochemical features, such as autofluorescence (golden yellow) and staining with stains for fat such as Sudan black (sudanophilia), although oil-red-O is more sensitive, PAS positiveness, and acid fastness (long Ziehl Neelsen technique). All of these characteristics increase in intensity with age for lipofuscin, but not for ceroid. Lipofuscin consists chiefly of proteins and lipids with very little carbohydrate, but lectin-binding histochemistry in human beings and rats has revealed differences in the saccharides of lipofuscin and ceroid.

52

53

Grossly, large amounts of lipofuscin in the heart and skeletal muscles impart a brown tinge. It is commonly seen in aged dairy cows sent to slaughter. Ceroid is grossly evident in the small intestine of dogs with so-called intestinal lipofuscinosis (Fig. 1-61) (see Chapter 7) and in nutritional panniculitis in cats, mink, foals, and pigs. Both these conditions are associated with a vitamin E deficiency and the ingestion of unsaturated fatty acids. In the dog the tunica muscularis, usually of the caudal small intestine, is discolored brown because of accumulations of ceroid in myocytes. In the cat with nutritional panniculitis, the subcutaneous fat is discolored lemon yellow to orange. This disease is considered to be the result of the ingestion of fish products with a high concentration of unsaturated fatty acids and a vitamin E deficiency, frequently brought about by the fats becoming rancid and destroying the vitamin E.

**Fig. 1-61 Ceroid, intestine, serosal surface, dog.** Note the brown discoloration of the muscular layer. The condition has been called intestinal lipofuscinosis but is not age related. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 1-1 Differences between Lipofuscin and Most Ceroid Pigments in Vivo

	Lipofuscin	Ceroid
Universality (invariably present in humans and all domestic animals)	Yes	No
Intrinsically (intracellularly in lysosomes of postmitotic and stable cells)	Yes	No
Time dependence	Yes	No
Initial occurrence	Infancy	Anytime
Deleteriousness	Never demonstrated	Frequent
Accumulation rate	Very slow	Usually rapid
Tissue distribution	Only intracellular	Intracellular and extracellular
Mode of formation	Mainly autophagy	Mainly heterophagy
Origin of precursors	Mainly intracellular	Mainly extracellular

From Porta EA: *Ann N Y Acad Sci* 959:57–65, 2002.

Microscopically, in routine H&E stained sections or in unstained sections, lipofuscin varies from a light golden brown to dark brown with advancing age. Because it is intralysosomal, it is perinuclear in neurons and in cardiac, skeletal, and smooth muscle myocytes. In feline nutritional panniculitis, globules of ceroid are extracellular in the interstitial tissue or have been ingested by macrophages and giant cells.

The significance of these two pigments is that lipofuscin is a clear indicator of the age of the cell and ceroid is a pathological pigment, often associated with vitamin E deficiency. Lectin binding histochemistry, which has shown differences between lipofuscin and ceroid from rats and human beings, may be applicable to differentiating these pigments in domestic animals, but it is a very laborious research tool and only provides semiquantitative data. Isolation and physicochemical analysis is more precise but even more laborious. Thus, until some other specific test becomes available, differentiation between the two pigments for diagnostic purposes will be based on the features listed in [Table 1-1](#).

### 1.14.3 HEMATOGENOUS PIGMENTS

This category includes hemoglobin, oxyhemoglobin, unoxygenated hemoglobin, methemoglobin, carboxyhemoglobin, hemosiderin, bilirubin, and hematin. Some are produced normally but can accumulate excessively (unoxygenated hemoglobin, hemosiderin, and bilirubin). Other pigments such as methemoglobin, carboxyhemoglobin, and hematin are pathological.

#### 1.14.3.1 HEMOGLOBIN

This normal pigment of erythrocytes can be responsible for gross changes in the color of the body.

Oxygenated hemoglobin is red and imparts the pink appearance to unpigmented skin and tissues. Normally, arterial blood (oxygenated hemoglobin) is red, and venous blood with more unoxygenated blood is bluish.

However, if the blood is not sufficiently oxygenated (unoxygenated hemoglobin), the tissues will appear blue, exhibiting so-called cyanosis ([Fig. 1-62](#)).

53

54

**Fig. 1-62 Cyanosis, feet, cat.** The footpads of the paw on the left are bluish due to unoxygenated hemoglobin, the result of a partial obstruction of the iliac artery at the aortic bifurcation by a saddle thrombus. Normal control paw on the right. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

In acute cyanide poisoning, cyanide binds to cytochrome oxidase, the enzyme in the cell responsible for oxidative phosphorylation, and this results in paralysis of cellular respiration. Tissues cannot use the oxygen delivered by the blood. Consequently, in acute cyanide toxicity the oxygen content and color of venous blood may be similar to those of arterial blood, and the venous blood will be bright red.

In carbon monoxide (CO) poisoning, as from exhaust gases from automobiles, the blood is a bright cherry red from the formation of carboxyhemoglobin ([Fig. 1-63](#)). Methemoglobin is an oxide of hemoglobin, in which the ferrous ion of hemoglobin is converted to the ferric ion, resulting in a reddish-brown (chocolate brown) color to the blood and tissue ([Fig. 1-64](#)). Methemoglobin is seen most often in poisoning by nitrites, especially following ingestion of nitrate-accumulating plants, but has been reported as a result of acetaminophen, naphthalene, local anesthetics (lidocaine, benzocaine, and tetracaine), and chlorates. It may also be congenital due to a genetic condition that occurs in human beings.

In intravascular hemolysis, hemoglobin is released from the lysed erythrocytes and stains the plasma pink. This hemoglobin may be excreted by the kidney, staining it dark red to reddish-black and the urine red ([Fig. 1-65](#)). Similar changes can result from myoglobinuria after the destruction of large numbers of myofibers (see [Chapter 15](#)).

Fig. 1-63 **Carbon monoxide (CO) poisoning, brain, human.** The blood in the brain is cherry red from the carboxyhemoglobin formed by the inhalation of CO in exhaust gases. (Courtesy Dr. J.C. Parker, School of Medicine, University of Louisville.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 1.14.3.2 HEMATINS

This category of pigments includes “formalin pigment” and the excreta of parasites, such as *Fascioloides magna* (liver fluke) and *Pneumonyssus simicola* (lung mite).

#### 1.14.3.2.1 Formalin Pigment

Formalin pigment, also called “acid formalin hematin,” is an annoying microscopic artefact that occurs when tissue rich in blood comes in contact with acid solutions of formalin, particularly if there has been a delay between death and fixation, allowing time for the erythrocytes to lyse and release their hemoglobin.

**Fig. 1-65 Acute hemolysis from chronic copper poisoning, kidney and urine, sheep.** The dark bluish color of the kidney and the dark red of the urine are caused by hemoglobin excreted via the kidney. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 1-66 Formalin pigment, blood.** Note the black spicules of hematin that lie between and on the erythrocytes, the result of fixation in unbuffered (acid) 10% formalin. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Grossly, formalin pigment is not visible because this change occurs only after fixation. Microscopically the pigment is brown to almost black, fine, and granular (Fig. 1-66), and can have birefringent spicules. It occurs mainly in blood vessels but also in other tissues where there are large accumulations of red blood cells. Pigment can lie between or on top of red blood cells and is negative for iron when stained by the Prussian blue reaction.

Because formalin pigment is formed only during fixation, it has no pathologic significance. Its significance is that it can interfere with the interpretation of histological sections. Fortunately it is easy to prevent its formation. Formalin pigment does not form if the pH of the fixative is above 6. Aqueous solutions of unbuffered formalin are highly acid. A common fixative is 10% buffered neutral formalin (really buffered neutral 10% formalin), which is buffered with a Sorensen phosphate buffer, and despite the name “neutral” has a pH of 6.8. It does not cause the formation of formalin pigment. Another commonly used and commercially available formalin fixative is Carson's fixative (also called modified Millionig's formalin fixative), with a pH of 7.3 and can be used as a dual-purpose fixative for both routine histopathologic and electron microscopic examinations. If formalin pigment is present in a tissue section, it can be removed by a variety of techniques including soaking the dewaxed tissue section before H&E staining in a saturated alcoholic solution of picric acid.

### 1.14.3.2.2

#### Parasite Hematin

The two most common causes of parasite hematin in veterinary medicine are *Fascioloides magna* (liver fluke) in ruminants and *Pneumonyssus simicola* in the lungs of macaques.

Parasite hematin from *Fascioloides magna* causes black tracts throughout the liver and is colloquially known as “flake exhaust” (Fig. 1-67, A). This lesion can be so severe as to affect the whole liver. Microscopically the black pigment accumulates adjacent to the migration tracts of the parasite and is phagocytosed by macrophages (Fig. 1-67, B). *Pneumonyssus simicola* produces a similar brown to black anisotropic pulmonary pigment presumed to be from the metabolism of hemoglobin by the parasite.

### 1.14.3.3

#### HEMOSIDERIN

Iron is stored in the body in two forms, ferritin and hemosiderin, both of which are protein-iron complexes. Ferritin is in all tissues, but the heaviest concentrations are found in the liver, spleen, bone marrow, and skeletal muscle. Hemosiderin is formed from intracellular aggregates of ferritin (Fig. 1-68). It appears as golden-yellow to golden-brown globules and is the most visible form of storage iron. Normally, most storage iron is found in the spleen.

Excess iron from the breakdown of senescent erythrocytes, or the result of a hemolytic crisis (e.g., because of autoimmune diseases or hemotropic parasites) or reduced erythropoiesis (malnutrition), is stored mainly in the spleen. Rarely in veterinary medicine, excess iron can be present in the body because of excessive absorption from the gut, multiple injections of iron, or from multiple blood transfusions.

Besides splenic storage, there may be local iron storage at sites of erythrocyte breakdown, such as in hemorrhages, and in areas of poor blood flow, as in chronic passive congestion of the lungs. In the latter case, because of the poor blood flow through the lungs, erythrocytes may come to the end of their natural life and be lysed or enter the alveoli by diapedesis, where they are phagocytosed by alveolar macrophages. These cells are termed “heart failure cells” (Fig. 1-69). Localized deposits of iron may also be present from the intramuscular injection of iron dextran, and this iron may drain to the regional lymph node.

Fig. 1-67 **Hematin pigment from *Fascioloides magna*, liver, ox.** **A**, Large areas of the liver are black from the pigment excreted by the fluke as it migrated through the liver. **B**, Hematin (black) pigment deposited in a fluke migration tract in the liver. H&E stain. (**A**, Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 1-68 **Hemosiderosis, liver, human being.** **A**, Hemosiderin is present as fine golden brown granules in hepatocytes H&E stain. **B**, Granules of hemosiderin are stained dark blue by the Prussian blue reaction, which is specific for iron. Prussian blue reaction. (**A and B**, From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Grossly, no change will be seen in an organ or tissue if there are only small amounts of hemosiderin, but very large amounts will cause a yellow to brown discoloration (Fig. 1-70). This color change can also be seen at sites of old bruises and other hemorrhages or hematomas. The spleen and the liver in hemolytic disease and the lungs in chronic passive congestion will also appear brown. Microscopically, hemosiderin deposits are golden-yellow to golden-brown globules, which may be intracellular or extracellular (Fig. 1-68, A). It can be

## Pathologic Basis of Veterinary Disease, 4th Edition

confirmed by the Prussian blue reaction (Fig. 1-68, *B*), which is sometimes incorrectly called a stain but is a chemical reaction, of which the end product is Prussian blue. In the acid solution that liberates ferric iron from the hemosiderin, the ferric iron is reacted with potassium ferrocyanide (colorless) to form ferric ferrocyanide, which is Prussian blue.

The significance of hemosiderin deposits depends on their location and the amount. Normally the spleen contains some hemosiderin, but excess hemosiderin is seen in the spleen and liver (Kupffer cells and hepatocytes) from hemolytic diseases, such as in autoimmune hemolytic anemia and hemotropic diseases such as babesiosis, anaplasmosis, or equine infectious anemia. Local tissue aggregations of hemosiderin are usually the result of the breakdown of erythrocytes in an old hemorrhage.

**Fig. 1-69 Chronic passive congestion, lung, dog. A,** Alveolar macrophages containing hemosiderin (*blue*) are present in the alveoli. Prussian blue reaction. **B,** The lungs have chronic passive congestion attributed to chronic left side heart failure. They are moderately firm and yellow-brown due to alveolar macrophages containing hemosiderin. Inflammatory mediators produced by these macrophages have induced fibroplasia and thus in the long term there has been extensive formation of interstitial collagen. This collagen is the reason the lungs have failed to collapse following incision of the diaphragm, which releases the negative pressure in the pleural cavity (note the rib impressions in the lung). (*A*, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. *B*, Courtesy College of Veterinary Medicine, University of Illinois.)

Fig. 1-70 **Subcutis, old bruise, leg, horse.** The display of colors—red, yellow, and brown—are due to hemoglobin, bilirubin, and hemosiderin, respectively, from the breakdown of the erythrocytes. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Excess hemosiderin is called hemosiderosis and must be differentiated from hemochromatosis, in which there are extreme accumulations of hemosiderin.

### 1.14.3.4 HEMATOIDIN

Grossly, hematoidin is yellow-brown to orange-red pigment derived from hemoglobin but free of iron. Hematoidin closely resembles bilirubin (see next section) but is formed by cells of the macrophage-monocyte system when they phagocytose and digest red blood cells and hemoglobin in areas of hemorrhage. Microscopically, hematoidin is crystalline and polarizes light.

### 1.14.3.5 BILIRUBIN

Low concentrations of bilirubin are normally present in the plasma from the breakdown of senescent erythrocytes (see [Chapter 13](#)). Briefly, when erythrocytes have come to the end of their natural life span

## Pathologic Basis of Veterinary Disease, 4th Edition

(average 70 days for a cat; average 150 days for cattle and horses), they are phagocytosed by the macrophage-monocyte system, chiefly by macrophages of the spleen and to a lesser extent by those of the bone marrow and liver (Kupffer cells). Within these cells the iron is removed and stored, and the remainder of the porphyrin ring is broken down to bilirubin, which is released into the blood where it attaches to albumin. This bilirubin-albumin complex is too large to be excreted by the kidney. It is carried to the liver, where it enters the space of Disse, where it is taken up by the microvilli of the hepatocytes, is conjugated to form bilirubin glucuronide or diglucuronide, and is then excreted into the bile canaliculus.

Icterus (jaundice), the yellow staining of the tissue by bilirubin, is the result of an imbalance between production and clearance of bilirubin, because there is either excess production or reduced clearance of bilirubin such that it accumulates in the plasma. The mutant Corriedale sheep model is an animal model for Dubin-Johnson syndrome in humans (Fig. 1-71).

Mechanisms leading to icterus can involve one or more of the following:

1. Excess production of bilirubin—as in hemolytic diseases such as babesiosis, anaplasmosis, and equine infectious anemia; or the breakdown of erythrocytes in a large hemorrhage such as a hematoma
2. Reduced uptake of bilirubin from the plasma by hepatocytes
3. Impaired or absent conjugation in hepatocytes, often a congenital or inherited abnormality, as in the Gunn rat
4. Hepatic necrosis. Because the cell membranes of several adjacent hepatocytes form the bile canaliculus, any necrosis of these cells will disrupt the wall of the canaliculus and allow leakage of bilirubin into the circulation. Extensive hepatic necrosis can cause icterus.
5. Decreased excretion of conjugated bilirubin by the hepatocytes into the bile canaliculus
6. Reduced flow of bile from the liver to the intestine caused by either intrahepatic or extrahepatic blockage of the biliary system

**Fig. 1-71 Defective bilirubin excretion, mutant Corriedale sheep, animal model for Dubin-Johnson syndrome.** Note the faint yellow discoloration of the lung from bilirubin. The other tissues are discolored dark green from phylloerythrin, which also has a similar defect in excretion from the liver. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Icterus is classified several different ways. A convenient approach uses the classification of prehepatic, hepatic, and posthepatic. The most common cause of prehepatic icterus is a hemolytic crisis, which produces high plasma concentrations of unconjugated bilirubin that exceed the uptake capacity of the hepatocytes. Hepatic icterus is caused by hepatocellular damage, which results in release of bilirubin, both conjugated and unconjugated into the blood and can be the result of one or more of factors 2 to 4. Posthepatic icterus is secondary to obstruction of the biliary system, either intrahepatic or extrahepatic (hepatic bile ducts and the common bile duct), with reflux of the conjugated bilirubin into the blood. In contrast to unconjugated bilirubin, which is carried in the blood attached to albumin and cannot be excreted by the kidney, conjugated bilirubin is excreted.

Grossly, icteric tissues are discolored yellow, and the color change is distributed systemically. Clinically, icterus is most easily recognized in lightly pigmented animals. In living animals, icterus is detected in mucous membranes of the oral cavity, urogenital systems, and alimentary system and in normally white areas, such as the sclera of the eyes. At necropsy, in addition to the sites listed previously, icterus can be identified in the omentum, mesentery, and adipose tissue (Fig. 1-72), except in Jersey and Guernsey cattle, horses, and nonhuman primates, whose sera and fat are normally discolored yellow by carotenoids. The intima of the large vessels is also a good site to detect icterus, and unless the plasma concentration is extremely high, the brain is usually unaffected.

58

59

**Fig. 1-72 Icterus, hemolytic anemia, abdominal and thoracic viscera, dog.**

The yellow discoloration from the bilirubin is particularly evident in fat and mesentery. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 1-73 Icterus. A,** Icterus, liver, cat. Note the enlarged liver with rounded edges and yellow-orange color caused by retained bilirubin. **B,** Bile casts in bile canaliculi. Acute hemolytic anemia, babesiosis, liver, cow. The bile casts are the result of a high rate of bilirubin excretion by the liver secondary to intravascular hemolysis. H&E stain. (**A,** *Courtesy the College of Veterinary Medicine, University of Illinois.* **B,** *Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Microscopically, icterus is not detected, but excessive quantities of bilirubin can be seen in the bile ducts and bile canaliculi in obstructive jaundice (Fig. 1-73).

Icterus is a very important clinical sign and may be detected by examination of the sclera, and in cases of anemia, in which the mucous membranes are pale, it may be visible there. Laboratory tests to determine the exact plasma or serum concentrations of bilirubin, and preferably whether or not it is conjugated, are essential. It is critical to realize that hyperbilirubinemia is not the same as icterus. Most domestic animals normally have very low serum concentrations of bilirubin, usually less than 1 mg/dl, except for the horse, in which it may range from 1 to 3 mg/dl; however, icterus is not detected until the serum concentration exceeds 1.5 mg/100 ml. Thus hyperbilirubinemia can be present without causing icterus.

### 1.14.3.6

#### PORPHYRIA

Congenital erythropoietic porphyria of calves, cats, and pigs is an inherited metabolic defect in heme synthesis caused by a deficiency of uroporphyrinogen III cosynthetase. The disease is sometimes incorrectly called osteohemachromatosis. It is also known colloquially as “pink tooth” because of the discoloration by the porphyrins accumulating in dentin and bone (Fig. 1-74). The teeth and bones of young animals are reddish (pink tooth), and those of adults are dark brown. In these cases both bones and teeth fluoresce red under ultraviolet radiation.

**Fig. 1-74 Pink tooth, congenital porphyria teeth, adult ox.** The teeth are discolored brown from the accumulation of porphyrins in the dentin. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 1.15 CELLULAR AGING\*

The common age-related diseases in animals include renal failure, osteoarthritis, muscle atrophy, cerebral atrophy from loss of cortical neurons, cessation of the growth of the teeth of horses, and loss of elasticity of the skin. The incidence of different causes of mortality in all domestic animals is not available, but data from laboratory beagles maintained for their life span are known. One quarter of these dogs died of neoplastic disease. Of the organ systems involved in the cause of death, the urinary system was responsible for 13%, the respiratory system for 6%, and the CNS for 7%. The leading cause of death from nonneoplastic diseases was renal failure. Death is often the end result of declining cell function, including cellular aging.

59

60

Shakespeare probably characterized aging best in his elegant description of the seven ages of man. It begins at the moment of conception, involves the differentiation and maturation of the organism and its cells, at some variable point in time leads to the progressive loss of functional capacity characteristic of senescence, and ends in death.

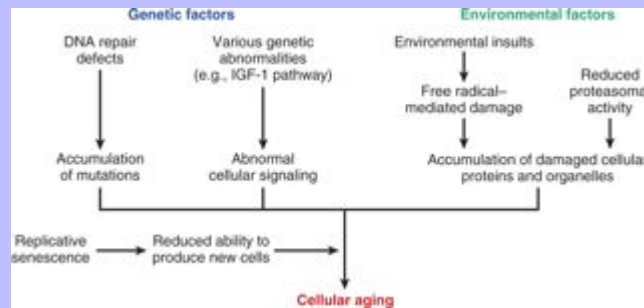

With age, there are physiologic and structural alterations in almost all organ systems. Aging in individuals is affected to a great extent by genetic factors, diet, social conditions, and occurrence of age-related diseases such as atherosclerosis, diabetes, and osteoarthritis (in human beings). In addition, there is good evidence that aging-induced alterations in cells are an important component of the aging of the organism. Here we discuss cellular aging because it could represent the progressive accumulation over the years of sublethal injury that may lead to cell death or at least to the diminished capacity of the cell to respond to injury.

Cellular aging is the result of a progressive decline in the proliferative capacity and life span of cells and the effects of continuous exposure to exogenous influences that result in the progressive accumulation of cellular and molecular damage (Fig. 1-75). These processes are reviewed next.

## Pathologic Basis of Veterinary Disease, 4th Edition

**Fig. 1-75 Mechanisms of cellular aging.** Genetic factors and environmental insults combine to produce the cellular abnormalities characteristic of aging. *IGF-1*, Insulin-like growth factor-1. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 1.15.1 STRUCTURAL AND BIOCHEMICAL CHANGES WITH CELLULAR AGING

A number of cell functions decline progressively with age. Oxidative phosphorylation by mitochondria is reduced, as is synthesis of nucleic acids and structural and enzymatic proteins, cell receptors, and transcription factors. Senescent cells have a decreased capacity for uptake of nutrients and for repair of chromosomal damage. The morphologic alterations in aging cells include irregular and abnormally lobed nuclei, pleomorphic vacuolated mitochondria, decreased ER, and distorted Golgi apparatus. Concomitantly, there is a steady accumulation of the pigment lipofuscin, which represents a product of lipid peroxidation and evidence of oxidative damage; advanced glycation end products, which result from nonenzymatic glycosylation and are capable of cross-linking adjacent proteins; and the accumulation of abnormally folded proteins. Advanced glycation end products are important in the pathogenesis of diabetes mellitus, but they may also participate in aging. For example, age-related glycosylation of lens proteins may underlie senile cataracts.

#### 1.15.1.1 REPLICATIVE SENESENCE

The concept that cells have a limited capacity for replication was developed from a simple experimental model for aging. Normal human fibroblasts, when placed in tissue culture, have limited division potential. Cells from children undergo more rounds of replication than cells from older people. In contrast, cells from patients with Werner syndrome, a rare disease characterized by premature aging, have a notably reduced in vitro life span. After a fixed number of divisions, all cells become arrested in a terminally nondividing state, known as cellular senescence. Many changes in gene expression occur during cellular aging, but a key question is which of these are causes and which are effects of cellular senescence.

How dividing cells can count their divisions is under intensive investigation. One likely mechanism is that with each cell division, there is incomplete replication of chromosome ends (telomere shortening), which ultimately results in cell cycle arrest. Telomeres are short repeated sequences of DNA (TTAGGG) present at the linear ends of chromosomes that are important for ensuring the complete replication of chromosome ends and for protecting chromosomal termini from fusion and degradation.

When somatic cells replicate, a small section of the telomere is not duplicated, and telomeres become progressively shortened. As the telomeres become shorter, the ends of chromosomes cannot be protected and are seen as broken DNA, which signals cell cycle arrest. The lengths of the telomeres are normally maintained by nucleotide addition, mediated by an enzyme called telomerase. Telomerase is a specialized RNA-protein complex that uses its own RNA as a template for adding nucleotides to the ends of chromosomes. The activity of telomerase is repressed by regulatory proteins, which restrict telomere elongation, thus providing a length-sensing mechanism. Telomerase activity is expressed in germ cells and is present at low levels in stem cells, but it is usually absent in most somatic tissue. Therefore as cells age, their telomeres become shorter and they exit the cell cycle, resulting in an inability to generate new cells to replace damaged ones. Conversely, in immortal cancer cells, telomerase is reactivated and telomeres are not shortened, suggesting that telomere elongation might be an important—possibly essential—step in tumor formation. Despite such alluring observations, however, the relationship of telomerase activity and telomeric length to aging and cancer still needs to be fully established.

\* Derived and modified slightly from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

### 1.15.2 GENES THAT INFLUENCE THE AGING PROCESS

Studies in *Drosophila*, *Caenorhabditis elegans*, and mice are leading to the discovery of genes that influence the aging process. Analyses of human beings with premature aging are also establishing the fundamental concept that aging is not a random process but is regulated by specific genes, receptors, and signals.

### 1.15.3 ACCUMULATION OF METABOLIC AND GENETIC DAMAGE

In addition to the importance of timing and a genetic clock, cellular life span may also be determined by the balance between cellular damage resulting from metabolic events occurring within the cell and counteracting molecular responses that can repair the damage. Smaller animals have generally shorter life spans and faster metabolic rates, suggesting that the life span of a species is limited by fixed total metabolic consumption over a lifetime.

One group of products of normal metabolism is reactive oxygen species. These by-products of oxidative phosphorylation cause covalent modifications of proteins, lipids, and nucleic acids. The amount of oxidative damage, which increases as an organism ages, may be an important component of senescence, and the accumulation of lipofuscin in aging cells is seen as the telltale sign of such damage. Consistent with this proposal are the following observations: (1) Variation in longevity among different species is inversely correlated with the rates of mitochondrial generation of a superoxide anion radical, and (2) overexpression of the antioxidative enzymes SOD and catalase extends the life span in transgenic forms of *Drosophila*. Thus part of the mechanism that times aging may be the cumulative damage that is generated by toxic by-products of metabolism, such as oxygen radicals. Increased oxidative damage could result from repeated environmental exposure to such influences as ionizing radiation, progressive reduction of antioxidant defense mechanisms (e.g., vitamin E and glutathione peroxidase), or both.

A number of protective responses counterbalance progressive damage in cells, and an important one is the recognition and repair of damaged DNA. Although most DNA damage is repaired by endogenous DNA repair enzymes, some persists and accumulates as cells age. Thus the balance between cumulative metabolic damage and the response to that damage could determine the rate at which we age. In this scenario, aging can be delayed by decreasing the accumulation of damage or by increasing the response to that damage.

## Pathologic Basis of Veterinary Disease, 4th Edition

Not only damaged DNA but damaged cellular organelles also accumulate as cells age. In part, this may be the result of declining function of the proteasome, the proteolytic machine that serves to eliminate abnormal and unwanted intracellular proteins.

In conclusion, it should be apparent that the various forms of cellular derangements and adaptations described in this chapter cover a wide spectrum, including adaptations in cell size, growth, and function; reversible and irreversible forms of acute cell injury; regulated type of cell death represented by apoptosis; pathologic alterations in cell organelles; and less ominous forms of intracellular accumulations, including pigmentations. Reference is made to all these alterations throughout this book because all organ injury and ultimately all clinical disease arise from derangements in cell structure and function.

## 2 Chapter 2 Vascular Disorders and Thrombosis

DEREK A. MOSIER

### 2.1 INTRODUCTION

Free-living unicellular organisms, such as amoebas, obtain nutrients and eliminate metabolic waste products directly into the external environment. In multicellular organisms, most cells do not have direct access to the external environment, and they require a circulatory system to deliver nutrients and remove their waste products. The movement of fluid and cells through the circulatory system links the external and local cell environments, and provides a means of communication between cells in complex, multicellular organisms. In this chapter, the basic abnormalities that affect fluid circulation and balance within an animal are described.

### 2.2 CIRCULATORY SYSTEM

The circulatory system consists of blood, a central pump (heart), blood distribution (arterial) and collection (venous) networks, and a system for exchange of nutrients and waste products between blood and extravascular tissue (microcirculation) (Fig. 2-1). A network of vessels (lymphatics) that parallel the veins also contribute to circulation by draining fluid from extravascular spaces into the blood vascular system.

The heart provides the driving force for blood distribution. Equal volumes of blood are normally distributed to the pulmonary circulation by the right side of the heart and the systemic circulation by the left side of the heart. The volume of blood pumped by each half of the heart per minute (cardiac output) is determined by the beats per minute (heart rate) and the volume of blood pumped per beat by the ventricle (stroke volume). Typically, each half of the heart pumps the equivalent of the entire blood volume of the animal per minute.

Arteries have relatively large diameter lumens to facilitate rapid blood flow with minimal resistance. The walls of arteries are thick and consist predominantly of smooth muscle fibers for tensile strength and elastic fibers for elasticity (Fig. 2-2). These fibers allow arteries to act as pressure reservoirs, expanding to hold blood ejected from the heart during contraction and passively recoiling to provide continuous flow and pressure to arterioles between heart contractions.

Arterioles are the major resistance vessels within the circulatory system; intravascular pressure can fall by nearly half after blood passes through the arterioles. Arterioles have relatively narrow lumens, the diameter of which is controlled by the smooth muscle cells that are the major component of their walls. Extrinsic sympathetic innervation and local intrinsic stimuli regulate the degree of arteriolar smooth muscle contraction, causing arterioles to dilate or constrict to selectively distribute blood to the areas of greatest need.

Capillaries are the site of nutrient and waste product exchange between the blood and tissue. Capillaries are the most numerous vessel in the circulatory system, with a total cross-sectional area nearly 1300 times that of the aorta. However, they normally contain only about 5% of the total blood volume. The velocity of blood flow through the capillaries is very slow, and red blood cells generally move through a capillary in single file to further facilitate the diffusion of nutrients and wastes. Capillaries have narrow lumens (approximately 8  $\mu\text{m}$ ) and thin walls (approximately 1  $\mu\text{m}$ ) consisting of a single epithelial cell layer (endothelium). At the junctions between capillary endothelia are interendothelial pores, which make the capillary semipermeable to facilitate diffusion of nutrients and waste products between the blood and tissues. There are three types of capillaries: continuous, fenestrated, and discontinuous. The basic functions and tissue locations of these types of capillaries are illustrated in Fig. 2-3. These

## Pathologic Basis of Veterinary Disease, 4th Edition

types of capillaries are central to disease processes in most organs, and they will be discussed in greater detail in the chapters covering the diseases of organ systems.

63

64

**Fig. 2-1 The vascular system.** Blood travels from the left side of the heart to the right side of the heart via the systemic circulation, and from the right side of the heart to the left side via the pulmonary circulation. Blood flow rate and pressure in the systemic arterial circulation decrease in conjunction with increased total arterial cross-sectional area. In the venous systemic circulation, blood flow rate, but not pressure, increases in conjunction with decreased total venous cross-sectional area. The flow, pressure, and cross-sectional area relationships are similar but reversed (i.e., veins deliver blood and arteries collect blood) in the pulmonary circulation. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

The return trip of blood to the heart begins in the postcapillary venules. Venules have a composition similar to capillaries but may have thin layers of muscle as they become more distant from the capillary bed. Arterioles,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

metarterioles, capillaries, and postcapillary venules are only visible microscopically, and they are collectively referred to as the microcirculation (Fig. 2-4).

Veins are composed mainly of collagen with smaller amounts of elastin and smooth muscle (Fig. 2-5). Venules and veins provide a low resistance pathway for the return of blood to the heart. Because of their distensibility, they can store large amounts of blood; nearly 65% of total blood volume is normally present within the systemic veins. Pressure and velocity of flow are low within venules and veins. Therefore other factors are necessary to help move venous blood toward the heart, such as venous valves to prevent backflow of blood, skeletal muscle contraction, venous vasoconstriction, an increased pressure gradient due to decreased pressure in the heart during filling (cardiac-suction effect), and decreased pressure in the thoracic veins due to negative pressure within the thoracic cavity (respiratory pump).

The lymphatic system originates as blind-ended lymphatic capillaries, which permeate the tissue surrounding the microcirculation (Fig. 2-4). Lymphatic capillaries have overlapping endothelial cells and large interendothelial gaps so that external pressure allows movement of fluid and molecules into the vessel. However, intravascular lymphatic pressure forces these overlapping edges together to prevent the flow of lymph back out of the vessel. Lymphatic capillary gaps are much larger than those between blood capillary endothelium, so they can accommodate movement of larger particles and substances. Lymphatic capillaries converge into progressively larger lymph vessels that drain into lymph nodes and then ultimately empty into the venous system. Similar to the venous vessels, lymphatics are low pressure, distensible vessels that require lymphatic valves and contraction of surrounding muscles to facilitate return of fluid to the blood.

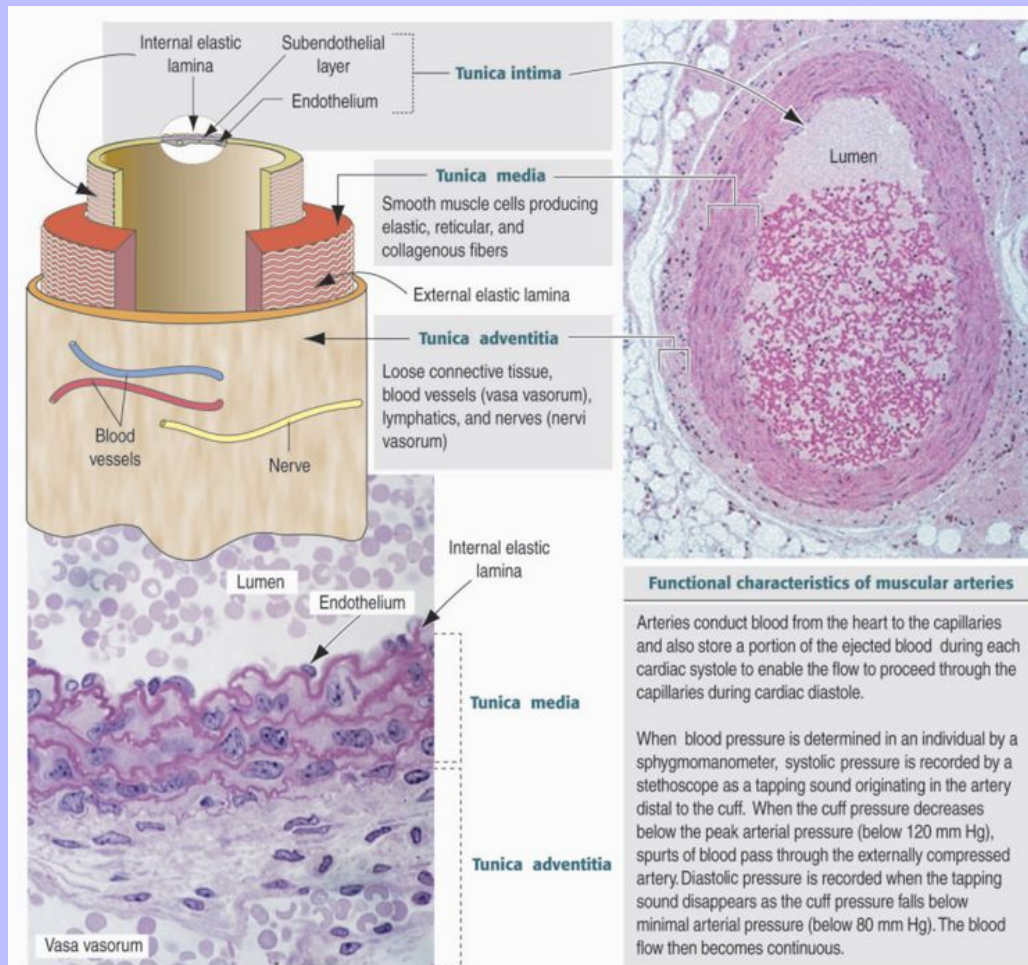

All components of the circulatory system are lined by a single layer of endothelium. Endothelium forms a dynamic and heterogenous interface between blood and tissue, and is also a critical participant in events such as fluid distribution, inflammation, immunity, angiogenesis, and hemostasis (Fig. 2-6). Normal endothelium has antithrombotic and profibrinolytic properties that maintain blood in a fluid state, but upon injury endothelium becomes prothrombotic and antifibrinolytic. This allows endothelium to respond locally to promote or restrict a host response to a specific area, while not affecting the normal function of endothelium and flow of blood in nonstimulated areas. Endothelial activation by oxidative stress, hypoxia, inflammation, infectious agents, tissue injury, or similar events results in the production and release of numerous substances with wide-ranging roles in physiology and pathology (Fig. 2-7, Box 2-1).

### 2.3 MICROCIRCULATION, INTERSTITIUM, AND CELLS

The exchange of fluid, nutrients, and waste products between blood and cells takes place through the interstitium, the space between cells and the microcirculation. The interstitium is composed of an extracellular matrix (ECM), which has structural, adhesive, and absorptive components. Type I collagen is the major structural component of the ECM and forms the framework in which cells reside. This is intimately associated with type IV collagen of cell basement membranes. Adhesive glycoproteins provide sites of attachment for structural components and also serve as receptors for cells, such as phagocytes and lymphocytes, which move through the interstitium. Absorptive disaccharide complexes (glycosaminoglycans) and protein-disaccharide polymer complexes (proteoglycans) are hydrophilic and can bind large amounts of water and other soluble molecules. In most cases, no more than 1.0 mm of interstitial space separates a cell from a capillary.

65

66

Fig. 2-3 Types of endothelium lining capillaries. (From Kierszenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)

**Fig. 2-4 The microcirculation.** The microcirculation consists of arterioles (small arteries proximal to a capillary bed), metarterioles (arterial capillaries), capillaries (thin, semipermeable vessels that connect arterioles and venules), and postcapillary venules (small vessels that merge to form veins after collecting blood from a capillary network). Smooth muscle of the arterioles and metarterioles regulates flow of blood into the capillary bed. There is a dramatic drop in pressure and blood flow rate from the arterial to the venous side of the microcirculation, facilitating interactions between capillary blood and interstitial fluid. Blind-ended lymphatic vessels that originate near capillary beds interact intimately with the microcirculation. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

### 2.4 FLUID DISTRIBUTION AND HOMEOSTASIS

The distribution of fluid, nutrients, and waste products between the blood, interstitium, and cells is controlled by physical barriers as well as pressure and concentration differences between each compartment. The cell's plasma membrane is a selective barrier that separates interstitial and intracellular compartments. Nonpolar (uncharged) lipid soluble substances such as  $O_2$ ,  $CO_2$ , and fatty acids move relatively freely across the plasma membrane based on concentration gradients. Polar (charged) lipid insoluble particles and molecules such as electrolytes, calcium, glucose, and amino acids enter the cell by carrier-mediated transport. Water readily moves across the plasma membrane down its concentration gradient. Although approximately 100 times the volume of water in a cell crosses the plasma membrane in 1 second, cell fluid content remains relatively stable because of the activity of energy-dependent membrane pumps (e.g.,  $Na^+/K^+$  adenosine triphosphatase [ATPase] pump) and the balance between osmotic pressures exerted by interstitial and intracellular solutes.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The capillary wall is a semipermeable barrier that influences the movement of fluid, nutrients, and waste products between the blood and interstitium. Lipid soluble substances can pass through capillary endothelium by dissolving in the membrane lipid bilayer, and large proteins can move through the cell by transport within vesicles. Most importantly, water and polar molecules move through interendothelial pores. Normally, these pores are large enough to allow the passage of water, small nutrients (ions, glucose, amino acids), and waste products, yet small enough to prevent the movement of cells and large proteins (albumin and other plasma proteins such as complement, kinin, and coagulation proteins). Local stimuli, such as inflammation, can cause endothelial cells to contract to widen interendothelial pores and allow the passage of larger molecules. Under normal conditions, the composition of plasma and interstitial fluid is very similar, with the exception of the large plasma proteins.

Movement of substances through interendothelial pores and cell membranes is generally passive in response to concentration and pressure gradients. Nutrient-rich arterial blood contains O<sub>2</sub>, glucose, and amino acids that move down their concentration gradients into the interstitium, where they are available for use by cells. CO<sub>2</sub> and waste products generated by cells accumulate in the interstitium and move down their gradient into the venous blood. These gradients become larger in areas where cells are metabolically active.

Water distribution between the plasma and interstitium is determined mainly by osmotic and hydrostatic pressure differentials between the compartments and is described by the following formula (Fig. 2-8):

$$\text{Net filtration across the endothelium} = K[(P_{\text{cap}} - P_{\text{int}}) - \sigma(\pi_{\text{cap}} - \pi_{\text{int}})]$$

K = Capillary endothelial permeability constant

P = Hydrostatic pressure

σ = Reflection coefficient

φ = Colloid osmotic pressure

cap = capillary

int = interstitium

Although sodium and chloride account for approximately 84% of the total osmolality of plasma, free movement of these electrolytes through interendothelial pores balances their concentrations in the plasma and interstitium, so their contribution to differences in osmotic pressure between these compartments is minimal. In contrast, nonpermeable, suspended plasma proteins comprise less than 1% of the total osmolality of plasma. However, because these proteins (particularly albumin) do not readily move through interendothelial pores, they exert a colloidal osmotic pressure that is responsible for the majority of the difference in osmotic pressure between the plasma and interstitium.

67

In the microcirculation, intravascular and interstitial osmotic pressures and interstitial hydrostatic forces remain relatively constant and favor intravascular retention of fluid. However, high hydrostatic pressures within the arteriolar end of the capillary bed result in a net filtration of fluid into the interstitium. Lower hydrostatic pressures in the venular end of the capillary bed result in a net absorption pressure and reentry of fluid into the microvasculature. Alternatively, filtration and absorption may not occur because of a drop in hydrostatic pressure across individual capillary beds. Instead, filtration may occur across the entire length of capillary beds with open precapillary sphincters and high rates of blood flow, whereas absorption may occur across the entire length of

69

## Pathologic Basis of Veterinary Disease, 4th Edition

capillary beds with closed precapillary sphincters and low blood flow rates. The slight excess of fluid that is retained in the interstitium and any plasma proteins that have escaped the vasculature enter lymphatic capillaries to be drained from the area.

### 2.4.1 Box 2-1 Endothelial Properties in Health and Disease: Endothelial Products

#### 2.4.1.1 FLUID DISTRIBUTION AND BLOOD FLOW

Semipermeable membrane for fluid distribution

- Interendothelial junctions

Vasodilation

- Nitric oxide
- Prostacyclin (PGI<sub>2</sub>)

2.4.1.2

Vasoconstriction

- Endothelin

### HEMOSTASIS

Antihemostatic substances

- PGI<sub>2</sub>
- Endothelial cell protein C receptor
- Tissue factor pathway inhibitor (TFPI)
- Tissue plasminogen activator
- Heparan sulfate
- Adenosine diphosphatase (ADPase) and adenosine triphosphatase (ATPase)
- Protein S

Prohemostatic substances

- von Willebrand's factor
- Tissue factor (TF) (factor III)
- Plasminogen activator inhibitor-1 (PAI-1)

2.4.1.3

### INFLAMMATORY MEDIATORS

Cytokines

- Interleukin (IL)-1, IL-6, IL-8

Enhanced expression of TF

Expression of leukocyte adhesion molecules:

- Cell adhesion molecule family
- Mucosal addressin cell adhesion molecule 1 (MAdCAM-1)
- Intercellular adhesion molecule 1 (ICAM-1),
- Vascular cell adhesion molecule 1 (VCAM-1)
- Platelet/endothelial cell adhesion molecule 1 (PECAM-1)
- Selectin family

- P-selectin

- E-selectin

2.4.1.4

### GROWTH FACTORS

Platelet-derived growth factor (PDGF)

Colony-stimulating factor (CSF)

Fibroblast growth factor (FGF)

Transforming growth factor- $\beta$  (TGF- $\beta$ )

Heparin

2.4.1.5

### FIBRINOLYSIS

Synthesis and secretion of fibrinolytic components under certain circumstances

Regulation of formation of plasmin

Tissue plasminogen activator (tPA)

Urokinase plasminogen activator receptor

Plasminogen activator inhibitor-1 (PAI-1)

Annexin II

**Fig. 2-8 Factors affecting fluid balance in the microcirculation.** Intravascular and interstitial hydrostatic and osmotic forces and lymphatic drainage are normally balanced so that there is no net loss or gain of fluid across the capillary bed. However, increased intravascular hydrostatic pressure or diminished plasma osmotic pressure leads to a net accumulation of extravascular fluid (edema). As the interstitial fluid pressure increases, tissue lymphatics remove much of the excess volume, eventually returning it to the circulation via the thoracic duct (except lymph from the head and neck, which is returned through the tracheal trunks and right lymphatic duct to empty into the cranial vena cava). If the ability of the lymphatics to drain tissue is exceeded, persistent tissue edema results. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The constant flow of fluid between the microcirculation and interstitium allows exchange of nutrients and waste products between these two fluid compartments to support cell functions. Additionally, the interstitium provides a fluid buffer to either increase or decrease the plasma volume to assure effective circulatory function. Excessive fluid intake will expand plasma volume and increase hydrostatic pressure, resulting in greater filtration into the interstitium to maintain a relatively constant plasma volume. Reduced fluid intake will decrease plasma volume, shifting the movement of water from the interstitium into the plasma to increase circulating fluid volume.

### 2.5 EDEMA (ABNORMAL FLUID DISTRIBUTION)

Alteration in any of the factors that regulate normal fluid distribution between the plasma, interstitium, and cells can lead to pathologic imbalances between these compartments.

70

#### 2.5.1 IMBALANCE BETWEEN INTRACELLULAR AND INTERSTITIAL COMPARTMENTS

Distribution of fluid between the interstitium and cells is generally dynamic but stable. This stability is necessary to maintain a relatively constant intracellular environment for cell function. Generalized conditions (such as alterations in plasma volume) and local stimuli (such as inflammation) can result in slight and usually transient

71

## Pathologic Basis of Veterinary Disease, 4th Edition

---

shifts in fluid distribution between the interstitium and cells. Excess plasma volume (hypervolemia) results in movement of additional water into the interstitium and ultimately into the cell along both osmotic and hydrostatic gradients to result in cell swelling. In contrast, reduced plasma volume (hypovolemia) can result in a flow of water in the opposite direction resulting in cell shrinkage and decreased interstitial volume. Increased interstitial volume will also cause a slight flow of fluid into cells in the affected region.

### 2.5.1.1 Box 2-2 Causes of Edema

#### 2.5.1.1.1 INCREASED VASCULAR PERMEABILITY

Vascular leakage associated with inflammation

Infectious agents

- Viruses (e.g., influenza and other respiratory viruses, canine adenovirus 1, equine and porcine arteriviruses, morbilliviruses)
- Bacteria (e.g., *Clostridium* sp., Shiga-like toxin–producing *Escherichia coli*, *Erysipelothrix rhusiopathiae*)
- Rickettsia (e.g., *Cowdria ruminantium*, *Ehrlichia risticii*, *Ehrlichia equi*, *Rickettsia rickettsii*)

Immune-mediated

- Type III hypersensitivity (e.g., feline infectious peritonitis, purpura hemorrhagica)

Neovascularization

Anaphylaxis (e.g., type I hypersensitivity to vaccines, venoms, and other allergens)

Toxins (e.g., endotoxin, paraquat, noxious gases, zootoxins)

Clotting abnormalities (e.g., pulmonary embolism, disseminated intravascular coagulation)

Metabolic abnormalities (e.g., microangiopathy due to diabetes mellitus, encephalomalacia due to thiamine deficiency)

#### 2.5.1.1.2 INCREASED INTRAVASCULAR HYDROSTATIC PRESSURE

Portal hypertension (e.g., right-side heart failure, hepatic fibrosis)

Pulmonary hypertension (e.g., left-side heart failure, high altitude disease)

Localized venous obstruction (e.g., gastric dilation and volvulus, intestinal volvulus and torsion, uterine torsion or prolapse)

Iatrogenic fluid overload

#### 2.5.1.1.3 DECREASED INTRAVASCULAR OSMOTIC PRESSURE

Decreased albumin production (e.g., malnutrition/starvation, debilitating diseases, severe hepatic disease)

## Pathologic Basis of Veterinary Disease, 4th Edition

2.5.1.1.4

Excessive albumin loss (e.g., gastrointestinal disease [protein-losing enteropathies] or parasitism [haemonchosis or trichostrongylosis in sheep], renal disease [protein-losing nephropathies], severe burns)

Water intoxication

### DECREASED LYMPHATIC DRAINAGE

Lymphatic obstruction or compression (e.g., inflammatory or neoplastic masses)

Congenital lymphatic aplasia or hypoplasia

Intestinal lymphangiectasia

Lymphangitis (e.g., paratuberculosis, sporotrichosis, epizootic lymphangitis of horses)

Disruption of any of the mechanisms that maintain proper fluid distribution between the cell and interstitium can have serious consequences for the cell. Failure to maintain proper osmotic balance as a result of cell membrane damage or failure of the energy-dependent plasma membrane pumps result in cell swelling, which if not quickly corrected can lead to cell death caused by osmotic lysis.

2.5.2

### IMBALANCE BETWEEN INTRAVASCULAR AND INTERSTITIAL COMPARTMENTS

Changes in distribution of fluid between the plasma and interstitium are most commonly manifested as edema, an accumulation of excess interstitial fluid. Edema occurs by four major mechanisms: (1) increased microvascular permeability, (2) increased intravascular hydrostatic pressure, (3) decreased intravascular osmotic pressure, and (4) decreased lymphatic drainage ([Box 2-2](#)).

71

2.5.3

### MECHANISMS OF EDEMA FORMATION

72

2.5.3.1

#### INCREASED MICROVASCULAR PERMEABILITY

Increased microvascular permeability is most commonly associated with the initial microvascular reaction to inflammatory or immunologic stimuli. These stimuli induce localized release of mediators that cause vasodilation and increased microvascular permeability. Immediate increases in permeability are induced by mediators such as histamine, bradykinin, leukotrienes, and substance P, which cause endothelial cell contraction and widening of interendothelial gaps. Subsequent release of cytokines such as interleukin-1 (IL-1), tumor necrosis factor (TNF), and  $\gamma$ -interferon induces cytoskeletal rearrangements within endothelial cells that result in endothelial cell retraction and more persistent widening of interendothelial gaps. Movement of intravascular fluid through these gaps into the interstitium results in localized edema that can dilute an acute inflammatory agent. The reaction terminates as localized edema and regresses when the stimulus is mild. However, most cases progress to the leakage of plasma proteins and emigration of leukocytes as early events in the formation of an acute inflammatory exudate.

2.5.3.2

#### INCREASED INTRAVASCULAR HYDROSTATIC PRESSURE

Increased intravascular hydrostatic pressure is most often due to increased blood volume in the microvasculature. This can be due to an active increased flow of blood into the microvasculature (hyperemia),

## Pathologic Basis of Veterinary Disease, 4th Edition

such as occurs with acute inflammation. But more commonly it results from passive accumulation of blood (congestion), often caused by heart failure or localized venous compression or obstruction. Increased microvascular volume and pressure cause increased filtration and reduced or even reversed fluid absorption back into the vessel. When increased hydrostatic pressure affects a localized portion of microvasculature, the edema is localized. In the case of heart failure, congestion and increased hydrostatic pressure can occur in the portal venous system (right heart failure) causing ascites; in the pulmonary venous system (left heart failure) causing pulmonary edema; or in both venous systems (generalized heart failure) causing generalized edema. Generalized edema can result in a reduction of circulating plasma volume, which activates a variety of volume-regulating compensatory responses. Plasma volume is increased through sodium retention induced by activation of the renin-angiotensin-aldosterone pathways, and water retention mediated by antidiuretic hormone (ADH) release following activation of intravascular volume and pressure receptors. The resulting intravascular volume overload further complicates the dynamics of fluid distribution that accompany heart failure.

2.5.3.3

### DECREASED INTRAVASCULAR OSMOTIC PRESSURE

Decreased intravascular osmotic pressure most commonly results from decreased concentrations of plasma proteins, particularly albumin. Hypoalbuminemia reduces the intravascular colloidal osmotic pressure resulting in increased fluid filtration and decreased absorption, culminating in edema. Hypoalbuminemia can result from either decreased production of albumin by the liver or excessive loss from the plasma. Decreased hepatic production most commonly occurs because of a lack of adequate protein for the synthetic pathway as a result of malnutrition or intestinal malabsorption of protein. Less often, severe liver disease with decreased hepatocyte mass or impaired hepatocyte function can result in inadequate albumin production. Loss of albumin from the plasma can occur in gastrointestinal diseases characterized by severe blood loss, such as that caused by parasitism. Renal disease in which glomerular and/or tubular function is impaired can result in loss of albumin into the urine. Plasma exudation accompanying severe burns is a less frequent cause of albumin loss. Due to the systemic nature of hypoalbuminemia, edema caused by decreased intravascular osmotic pressure tends to be generalized.

2.5.3.4

### DECREASED LYMPHATIC DRAINAGE

Decreased lymphatic drainage reduces the ability of the lymphatic system to remove the slight excess of fluid that normally accumulates in the interstitium during fluid exchange between the plasma and interstitium. This can occur because of lymph vessel compression by a neoplastic or inflammatory swelling, lymph vessel constriction caused by fibrosis, or internal blockage of a lymph vessel by a thrombus. Edema occurs once the capacity of the damaged lymphatics is exceeded and is localized to the area served by the affected lymphatic vessels.

2.5.4

### MORPHOLOGIC CHARACTERISTICS OF EDEMA

Edema is morphologically characterized by clear to slightly yellow fluid that generally contains a small amount of protein (transudate), which thickens and expands affected interstitium (Fig. 2-9). When edema occurs in tissues adjacent to body cavities or open spaces, such as alveolar lumens, the increased interstitial pressure often forces fluid into these cavities and spaces. The result can be fluid within alveolar lumens (pulmonary edema) (Fig. 2-10), the thoracic cavity (hydrothorax), the pericardial sac (hydropericardium), or the abdominal cavity (ascites or hydroperitoneum) (Fig. 2-11). Histologically, edema is an amorphous, pale eosinophilic fluid (hematoxylin and eosin [H&E] stain) because of its protein content (Fig. 2-12). The clinical significance of edema is variable, depending mainly on its location. Subcutaneous edema results in doughy to fluctuant skin and

72

73

## Pathologic Basis of Veterinary Disease, 4th Edition

---

subcutis that is often cooler than adjacent nonaffected tissue, but alone has minimal clinical impact (Fig. 2-13). Likewise, ascites does not generally have an impact on the function of abdominal organs. In contrast, edema of a tissue within a confined space, such as the brain in the cranial vault, can result in pressure within the organ that results in serious organ dysfunction. Similarly, filling a confined space with fluid, such as in hydrothorax or hydropericardium, can have a substantial impact on the function of the lungs and heart, respectively. In these situations edema can have immediate and life-threatening implications.

**Fig. 2-9 Edema, intestine, submucosa, horse.** Note the clear to slightly yellow fluid (that generally contains a small amount of protein [transudate]), which thickens and expands the affected submucosa. (Courtesy Department of Veterinary Biosciences, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 2-10 Pulmonary edema, lung, pig.** The lung failed to collapse and has a firm rubbery texture attributable to edema fluid in alveoli and the interstitium. Note the prominent interlobular septa caused by edema (arrowhead) and the frothy edema fluid exuding from the bronchus (arrow). (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 2-11 **Ascites (hydroperitoneum), peritoneal cavity, dog.** Slightly yellow fluid is present in the peritoneal cavity. When edema occurs in tissue adjacent to body cavities, the increased interstitial pressure forces the edema fluid, which is usually clear to slightly yellow (transudate), into these cavities. (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

Fig. 2-12 **Pulmonary edema, lung, rat.** There is eosinophilic (pink staining) fluid distending the alveoli in the lower specimen. Histologically, edema is an amorphous, pale eosinophilic fluid, and the depth of the eosinophilia is proportional to its protein content. The fluid in this specimen has a high protein content. The upper specimen is normal rat lung. H&E stain. (Courtesy Dr. A. López, Atlantic Veterinary College; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 2.6 HEMOSTASIS

Hemostasis is the arrest of bleeding. It is a physiologic response to vascular damage and provides a mechanism to seal an injured vessel to prevent blood loss (hemo = blood, stasis = halt, slow). Hemostasis is a finely regulated process that predominantly involves interactions between endothelium, platelets, and coagulation factors. It normally occurs only at the site of vascular injury, without affecting fluidity and flow of blood in normal undamaged vasculature. Disruption of the delicate balance of hemostasis can result in the pathologic states of blood loss (hemorrhage) or inappropriate thrombus formation (thrombosis).

73

74

**Fig. 2-13 Subcutaneous edema, congenital lymphedema, skin, dog.** This form of edema results in doughy to fluctuant skin and subcutis. Edematous skin is often cooler than adjacent nonaffected skin. In congenital lymphedema the lymph vessels are hypoplastic or aplastic. (Courtesy Dr. H. Liepold, College of Veterinary Medicine, Kansas State University.)

Normal endothelium provides a surface that promotes the smooth, nonturbulent flow of blood. It produces and responds to mediators that enhance vasodilation and inhibit platelet adhesion, aggregation, and coagulation. In contrast, following injury or activation, endothelium produces or responds to mediators that induce vasoconstriction, enhance platelet adhesion and aggregation, and stimulate coagulation (Box 2-3).

Platelets are anucleate cell fragments derived from megakaryocytes. Their major role in hemostasis is to form the initial plug that covers and seals a small area of vascular damage. Following vascular damage, platelets adhere to subendothelial collagen and other ECM components (e.g., fibronectin, adhesive glycoproteins, and proteoglycans). Adhered platelets express receptors that promote aggregation of additional platelets and become activated to release

## Pathologic Basis of Veterinary Disease, 4th Edition

the products of their cytoplasmic granules and produce other mediators of coagulation (e.g., thromboxane) (Box 2-4). The phospholipid surfaces of aggregated platelet membranes also serve to promote coagulation.

Coagulation factors are plasma proteins produced mainly by the liver. Their purpose in hemostasis is to form fibrin. Coagulation factors are divided into: (1) a structurally related and functionally interdependent contact group (prekallikrein, high molecular weight kininogen [HMWK], and factors XII and XI); (2) a vitamin K–dependent group (factors II, VII, IX, and X); and (3) a highly labile fibrinogen group (factors I, V, VIII, and XIII). Circulating coagulation factors are activated in a cascade fashion by hydrolysis of arginine- or lysine-containing peptides to convert them to enzymatically active serine proteases (except for factor XIII, which has cysteine-rich active sites). The contact group factors are activated by contact with collagen or subendothelial components to initiate coagulation by the intrinsic pathway. The extrinsic pathway of coagulation is activated by release of tissue factor (TF, factor III) from damaged cells. The vitamin K–dependent coagulation factors play an important role in localizing coagulation by  $\gamma$ -carboxylating glutamic acid residues of N-terminal ends of precursor factors so that they can bind calcium to form calcium bridges with platelet phospholipids.

### 2.6.1 HEMOSTATIC PROCESS

The sequence of events that contribute to hemostasis are: (1) transient vasoconstriction and platelet aggregation to form a platelet plug at the site of damage (primary hemostasis), (2) coagulation to form a meshwork of fibrin (secondary hemostasis), (3) fibrinolysis to remove the platelet/fibrin plug (thrombus retraction), and (4) tissue repair at the damaged site (Fig. 2-14).

#### 2.6.1.1 PRIMARY HEMOSTASIS

Primary hemostasis includes the initial vascular and platelet response to injury. Neurogenic stimuli and mediators released locally by endothelium and platelets causes vasoconstriction immediately following damage (Fig. 2-14, A). The nature and effectiveness of vasoconstriction is partially determined by the size of the affected vessel, the amount of smooth muscle it contains, and endothelial integrity. Narrowing of the vessel lumen allows opposing endothelial surfaces to come into contact with and sometimes adhere to each other to reduce the volume of blood flowing through the damaged area. Platelets can directly adhere to the exposed subendothelial matrix of collagen, fibronectin, and other glycoproteins and proteoglycans (Fig. 2-14, B). However, more efficient adhesion occurs when von Willebrand's factor released by local activated endothelium coats subendothelial collagen to form a specific bridge between collagen and platelet receptor GpIb. At this stage and without further stimulation, adhered and aggregated platelets may disaggregate.

74

75

Otherwise, platelets within the aggregate secrete the contents of their dense bodies and  $\alpha$ -granules and produce substances such as thromboxane to accelerate hemostasis. Adenosine diphosphate (ADP) released from dense granules triggers the binding of fibrinogen to platelet receptor GpIIb-IIIa, resulting in the formation of bridges that link platelets into a loose aggregate. Platelet contraction consolidates this loose aggregate into a dense plug, which covers the damaged area. When vascular injury is minimal, platelet plugs alone may resolve the damage. If not, the exposed collagen and aggregated platelet phospholipids promote secondary hemostasis at the site.

#### 2.6.1.1.1.3.3 Transforming Growth Factor- $\beta$ (TGF- $\beta$ )

Modulates vascular repair by inhibition of proliferation of various cell types, including endothelium

### 2.6.1.2 SECONDARY HEMOSTASIS

In most cases of vascular damage, the formation of fibrin is important for the prevention of blood loss. Fibrin is the end-product of a series of enzymatic reactions involving coagulation factors, nonenzymatic cofactors, calcium, and phospholipid membranes derived mainly from platelets (Fig. 2-14, C). Three integrated pathways have been classically used to describe the coagulation process and formation of fibrin. The cascade model of coagulation provides a useful starting point for understanding coagulation (Figs. 2-15 and 2-16). However, more recent concepts of coagulation emphasize the interrelatedness of these pathways, the multiple positive and negative control loops within the system, and amplification of the process on affected cell surfaces.

#### 2.6.1.2.1 Intrinsic Pathway

Intrinsic coagulation is a complex and highly interrelated process that is initiated by the contact group of coagulation factors (Figs. 2-15 and 2-16). Prekallikrein and factor XI normally circulate bound to HMWK, which acts as a catalytic factor for their activation. Following vascular injury, circulating prekallikrein-HMWK and factor XII form a complex on negatively charged endothelial or subendothelial

75

76

## Pathologic Basis of Veterinary Disease, 4th Edition

---

surfaces, which results in activation of factor XII (factor XIIa). Factor XIIa initiates a complex series of reactions that affect coagulation as well as kinin formation, complement activation, and fibrinolysis. Factor XIIa activates factor XI (XIa) and interacts with prekallikrein to form kallikrein, and interacts with HMWK to form kinins. Cleavage of factor XIIa by kallikrein, plasmin, and other proteolytic enzymes forms fragments (factor XII<sub>f</sub>), which have activity that is similar to, but much weaker than, factor XIIa. Both kallikrein and factor XIa with Ca<sup>2+</sup> can activate factor IX (factor IXa). Factor IXa then binds to platelet phospholipids in a complex with Ca<sup>2+</sup> and factor VIII. Following modification of factor VIII by thrombin into factor VIIIa, this complex of factor VIIIa-factor IXa/Ca<sup>2+</sup>-phospholipid (tenase) activates factor X to initiate the common coagulation pathway.

2.6.1.2.2

### Extrinsic Pathway

Release of factor III (TF) from cells underlying damaged endothelium, or from activated endothelium, initiates the extrinsic pathway (Figs. 2-15 and 2-16). TF is a high molecular weight phospholipid-containing glycoprotein found in the plasma membrane of many cells, including activated, but not resting, endothelium. Endothelial cell production of TF is stimulated by substances such as endotoxin, TNF, IL-1, transforming growth factor- $\beta$  (TGF- $\beta$ ), and thrombin. When circulating factor VII comes into contact with TF, it forms a  $\text{Ca}^{2+}$ -dependent TF:VII complex on the TF-expressing surface. Although this complex may have some enzymatic activity, activation of factor VII by substances such as factors XIIa, XIIIf, IXa, Xa, IIa, and kallikrein results in the much more active TF:VIIa complex. This complex along with  $\text{Ca}^{2+}$  activates factor X to initiate the common pathway.

2.6.1.2.3

### Common Pathway

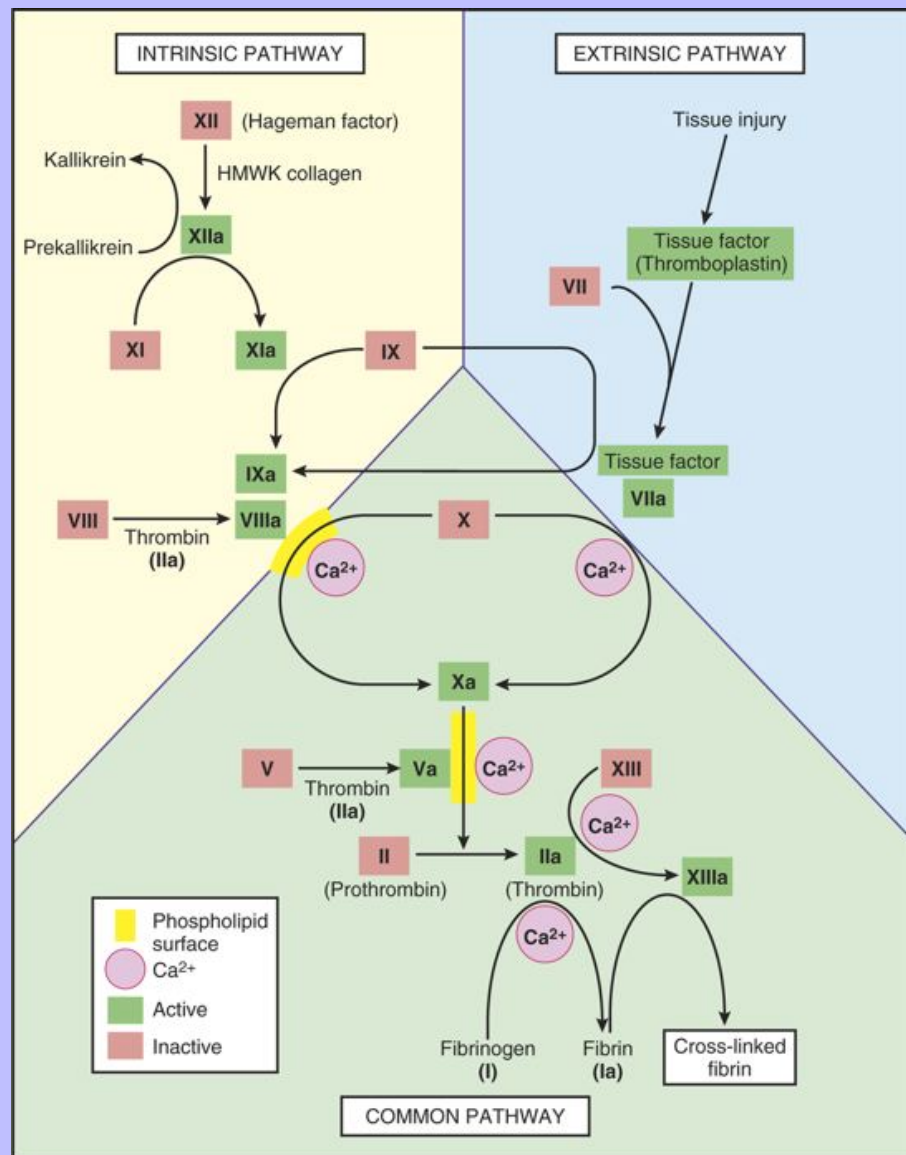

The intrinsic and extrinsic pathways merge with the activation of factor X (Figs. 2-15 and 2-16). Factor Xa is bound to endothelial or platelet membrane phospholipids where it can directly convert factor II into factor IIa (thrombin). However, when factor Xa is combined with factor Va and  $\text{Ca}^{2+}$  (prothrombinase complex), this reaction occurs much more rapidly. Thrombin is a multifunctional mediator whose major function is to cleave fibrinopeptides A and B from factor I (fibrinogen) to form fibrin monomers (Fig. 2-17). Removal of these fibrinopeptides reduces intermolecular repulsive forces so that fibrin monomers

77

spontaneously form weak  $\text{H}^+$  bonds and self-polymerize into soluble fibrin polymers. Factor XIIIa, formed by the action of factors Xa and IIa on factor XIII, along with  $\text{Ca}^{2+}$ , catalyzes the formation of covalent bonds that cross-link adjacent fibrin molecules to make the polymer insoluble. Cross-linking of the fibrin network, along with concurrent platelet contraction and the presence of abundant calcium, thrombin, and adenosine triphosphate (ATP), causes retraction of the fibrin-platelet thrombus. Retraction reduces the size of the thrombus to allow blood flow to continue and to pull damaged vessel edges closer together for efficient healing.

78

Fig. 2-15 **The coagulation cascade.** Note the common link between the intrinsic and extrinsic pathways at the level of factor IX activation. Factors in red boxes represent inactive molecules; activated factors are indicated with a lower case “a” and a green box. *PL*, Phospholipid surface; *HMWK*, high molecular weight kininogen. Not shown are the anticoagulant inhibitory pathways. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### INTEGRATED MODEL OF COAGULATION

In vivo coagulation is more like an integrated web rather than a series of independent cascades. The major stimulus for coagulation in vivo is exposure of plasma to TF and subsequent extrinsic coagulation. Two important events occur following the formation of the TF/factor VIIa complex on damaged, TF-expressing surfaces. Factor X is activated as described for the common pathway, and factor IX is activated to allow a bypass of the contact phase of classical intrinsic coagulation. Factor Xa remains localized upon the damaged cell surface to initiate the formation of a small amount of thrombin. Although the amount of thrombin generated is insufficient to convert significant amounts of fibrinogen into fibrin, it does activate platelets and factors V, VIII, XI, and XIII on TF-expressing surfaces. Factor IXa can bind to the surface of activated platelets in the area to initiate the formation of tenase complexes, which activates additional factor X of the common pathway. Thrombin-activated or intrinsically activated factor XIa can also participate by activating additional factor XI upon platelet surfaces. The thrombin-initiated activation of these different factors provides an amplification of the critical reactions necessary to generate large amounts of thrombin for the subsequent conversion of fibrinogen into fibrin. Other, probably less important links between the pathways also exist. For example, intrinsic factors XIIa, XII<sub>f</sub>, and IXa, and kallikrein can activate extrinsic factor VII to provide additional amplification of this pathway.

78

79

**Fig. 2-16 Coagulation, fibrinolysis, and other pathways are highly integrated to balance the host response to injury.** Intrinsic coagulation is initiated by binding of high molecular weight kininogen (HMWK), factor XII, and prekallikrein (pK) to altered endothelial surfaces. Activated products of this reaction (factor XIIa and kallikrein [K]) directly or indirectly result in the formation of factor XIa (intrinsic coagulation pathway), factor VIIa (extrinsic coagulation pathway), plasmin (Pa) (fibrinolysis), and complement fragments C3a, C3b, C5a (complement cascade). Extrinsic coagulation is initiated by release of tissue factor (TF) from areas of damaged endothelium, with subsequent binding of TF to factor VII. The TF:VII complex can be activated by a wide variety of agents. Activation of factor X initiates the common cascade to ultimately result in cleavage of fibrinogen into fibrin. In addition to its role in the common pathway, factor IIa (thrombin) also influences both the intrinsic (factors XI and VIII) and extrinsic (TF:VII) coagulation pathways. Additional interactions between these factors, which are not shown in the figure, are described in the text. Specific effects of kallikrein include cleavage and activation of factors XII, IX, and VII, plasminogen, HMWK, and complement fragment C5. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

**Fig. 2-17 The central roles of thrombin in hemostasis and cellular activation.** In addition to a critical function in generating cross-linked fibrin (via cleavage of fibrinogen to fibrin and activation of factor XIII), thrombin also directly induces platelet aggregation and secretion (e.g.,  $\text{TXA}_2$ ). Thrombin also activates endothelium to generate leukocyte adhesion molecules and a variety of fibrinolytic (*tPA*), vasoactive (*NO*, *PGI<sub>2</sub>*), or cytokine (*PDGF*) mediators. Likewise, mononuclear inflammatory cells may be activated by the direct actions of thrombin. *ECM*, Extracellular matrix; *NO*, nitric oxide; *PDGF*, platelet-derived growth factor; *PGI<sub>2</sub>*, prostacyclin;  $\text{TXA}_2$ , thromboxane  $\text{A}_2$ ; *tPA*, tissue plasminogen activator. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The interrelatedness of coagulation pathways also extends to anticoagulant reactions. When excessive levels of thrombin are generated, thrombin destroys rather than activates factors V and VIII. When thrombin binds to thrombomodulin on endothelial surfaces, it activates protein C, a potent anticoagulant (see Coagulation Inhibitors). Intrinsic pathway factors XIIa, XIIf, and XIa, and kallikrein not only participate in fibrin formation but also initiate fibrinolysis by cleaving plasminogen into plasmin (see Thrombus Dissolution, next).

79

80

## 2.6.2 THROMBUS DISSOLUTION

The purpose of a fibrin-platelet thrombus is to form a temporary patch that is dissolved following healing of the vessel (thrombolysis). The rate of dissolution must be balanced so that it does not occur so quickly that bleeding returns but is not prolonged so that vessel occlusion may occur (Fig. 2-18). Fibrin dissolution (fibrinolysis) is initiated immediately upon vessel injury by the cleavage of the plasma protein plasminogen into plasmin (Fig. 2-19). Plasminogen is activated by a wide variety of proteases, including activated contact group coagulation factors, plasminogen activators present within endothelium and other tissues (tissue plasminogen activator, tPA), and activators present in secretions and fluids. Plasminogen adsorbs to fibrin within a thrombus, so that upon activation the plasmin is localized to the site of the thrombus. The presence of fibrin increases the efficiency of tPA-dependent plasmin generation by nearly twofold. Additionally, by binding to fibrin, plasmin is protected from its major inhibitor ( $\alpha_2$ -antiplasmin). The bound plasmin restricts thrombus size by degrading both cross-linked (insoluble) fibrin within the thrombus and fibrinogen, so that additional fibrin formation is inhibited. Dissolution of insoluble, but not soluble, fibrin by plasmin results in the formation of fibrin degradation products (FDPs). FDPs are various-sized fragments of fibrin and fibrinogen that can impair hemostasis. Collectively, FDPs inhibit thrombin, interfere with fibrin polymerization, and can coat platelet membranes to inhibit platelet aggregation.

**Fig. 2-18 Schematic illustration of some of the procoagulant and anticoagulant activities of endothelial cells.** Not shown are the profibrinolytic and antifibrinolytic properties. vWF, von Willebrand's factor;  $PGI_2$ , prostacyclin; NO, nitric oxide; tPA, tissue plasminogen activator. Thrombin receptor is referred to as protease activated receptor (PAR). (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 2.6.3 REGULATION OF HEMOSTASIS

The potent biologic effects of hemostatic products must be finely regulated to achieve appropriate hemostasis, without creating detrimental effects associated with too little or too much activity. Coagulation factors are continuously activated at a low, basal level to keep the system primed for a rapid response to an injurious stimulus. Proteins that inhibit or degrade activated hemostatic products are present in the plasma or are locally produced at the site of hemostasis (Fig. 2-19). These products help confine hemostasis to a site of vascular damage and inhibit hemostatic reactions in normal vasculature. Regulation is also achieved by simple dilution of activated agents as blood removes them from the area, and the factors are removed from the circulation by the liver and spleen.

80

81

**Fig. 2-19** The fibrinolytic system, illustrating the plasminogen activators and inhibitors. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

#### 2.6.3.1 COAGULATION INHIBITORS

The major anticoagulant-antithrombotic systems upon endothelial cells are the protein C-protein S-thrombomodulin system and endothelial heparan sulfate to which antithrombin III (ATIII) and tissue factor pathway inhibitor (TFPI) are bound. ATIII is the most potent and clinically significant of the coagulation inhibitors, accounting for nearly 80% of the thrombin-inhibitory activity of plasma. ATIII is a circulating serine protease produced by endothelium and hepatocytes that will degrade all activated coagulation factors except for factor VIIa. However, its most important action is the neutralization of thrombin and factor Xa. ATIII can bind heparan sulfate present on the surface of normal endothelium and platelets to localize it to the site where it is most needed to inactivate thrombin and factor Xa. Through this binding, heparin accelerates the rate of ATIII-induced serine protease inactivation by 2000- to 10,000-fold. ATIII also inhibits fibrinolysis (by inhibiting plasmin and kallikrein), kinin formation, and complement activation. Although the major role of heparin is to bind and enhance the activity of ATIII, it also inhibits coagulation by enhancing the release of TFPI from endothelial cells and interfering with binding of platelet receptors to von Willebrand's factor.

The protein C pathway also plays a critical role in preventing thrombosis. Proteins C and S are vitamin K-dependent glycoproteins that, when complexed together on phospholipid surfaces, potently inhibit coagulation by destroying factors Va and VIIIa. An important step in this process is the activation of protein C by thrombin, a reaction that normally occurs at low levels but that increases nearly 20,000-fold following the

## Pathologic Basis of Veterinary Disease, 4th Edition

binding of thrombin to the endothelial receptor thrombomodulin. This reaction is further enhanced by the presence of a protein C receptor on the surface of endothelial cells. Protein S, in addition to serving as a nonenzymatic cofactor with protein C, can independently inhibit factors VIIIa, Xa, and Va. Binding of thrombin to thrombomodulin also results in the loss of the procoagulant functions of thrombin. The protein C-S complex may also enhance fibrinolysis by neutralizing plasminogen activator inhibitors.

TFPI is a significant inhibitor of extrinsic coagulation, which functions synergistically with protein C and ATIII to suppress thrombin formation. TFPI is a plasma protein derived mainly from endothelium and smooth muscle cells that forms a complex with factor Xa on the endothelial-bound TF:VIIa molecule to inhibit subsequent factor X activation. TFPI can interact with VIIa without Xa, but at a slow rate. Therefore TFPI does not substantially inhibit extrinsic coagulation until factor Xa levels increase, after which TFPI provides negative feedback for further generation of Xa by the TF:VIIa complex.

2.6.3.2

### FIBRINOLYTIC INHIBITORS

Major inhibitors of fibrinolytic agents include plasminogen activator inhibitor-1 (PAI-1) and antiplasmins, which include  $\alpha_2$ -antiplasmin,  $\alpha_2$ -macroglobulin,  $\alpha_1$ -antitrypsin, antithrombin III, and C-1 inactivator. PAI-1 inhibits tPA and urokinase, therefore inhibiting fibrinolysis and promoting fibrin stabilization. PAI-1 also inactivates activated protein C, plasmin, and thrombin. The antiplasmins function in a cooperative fashion to prevent excessive plasmin activity so that a thrombus can dissolve at a slow and appropriate rate.

81

82

$\alpha_2$ -Antiplasmin is the first to bind and neutralize plasmin. When its binding capacity is saturated, excess plasmin is taken up by  $\alpha_2$ -macroglobulin.  $\alpha_2$ -Macroglobulin also binds to certain activated factors, such as thrombin, and physically entraps but does not degrade their active sites. When  $\alpha_2$ -macroglobulin is saturated, plasmin binds to  $\alpha_1$ -antitrypsin.  $\alpha_1$ -Antitrypsin is a weak inhibitor of fibrinolysis, but a potent inhibitor of factor XIa. In addition to their fibrinolytic roles,  $\alpha_1$ -antitrypsin and  $\alpha_2$ -macroglobulin are the major plasma inhibitors of activated protein C.

2.6.4

### HEMOSTATIC INTEGRATION WITH OTHER HOST RESPONSES

Hemostatic pathways are highly integrated, and many factors within the pathways have multiple roles. Thrombin has a major procoagulant role to cleave factor I to yield fibrin monomers. Thrombin also activates factors V, VIII, XI, and XIII, and is a potent activator of platelets. In contrast, high concentrations of thrombin destroy, rather than activate, factors V and VIII. When thrombin binds to thrombomodulin on endothelial surfaces, it activates protein C, a potent anticoagulant.

A prothrombotic environment is also proinflammatory. Inflammatory stimuli, such as IL-1 and TNF, activate endothelium to produce TF and to increase their expression of leukocyte adhesion molecules. Thrombin and histamine released by degranulating mast cells also stimulate the expression of the adhesion P-selectin. In early stages of inflammation, leukocytes can loosely attach and roll along endothelium or adhered platelets by interacting with endothelial or platelet P-selectin. During this interaction the neutrophil  $\alpha_M\beta_2$  integrin may bind to fibrinogen bound to GPIIb/IIIa on the surface of activated platelets to promote the conversion of fibrinogen into fibrin. An enhanced prothrombotic environment during inflammation also occurs because of decreased thrombomodulin function in response to inflammatory products such as endotoxin, IL-1, TNF, and TGF- $\beta$ . Additionally, adhered or migrating neutrophils and platelets can release lysosomal proteases (e.g., elastase, collagenase, and acid hydrolases), which cleave many products upon the endothelial or platelet surfaces. The conversion of prekallikrein to kallikrein during the contact phase of intrinsic coagulation is another source of integration between hemostatic, fibrinolytic, and inflammatory pathways. Kallikrein is chemotactic, can directly

## Pathologic Basis of Veterinary Disease, 4th Edition

cleave C5 to C5a and C5b, and can cleave HMWK to form bradykinin. The major fibrinolytic protein plasmin also influences other host responses by cleaving C3 to generate C3a and C3b. Mitogenic factors produced by activated endothelium and platelets (e.g., platelet-derived growth factor [PDGF], TGF- $\beta$ , and vascular endothelial growth factor [VEGF]) contribute to the healing of the damaged tissue. These are just a few of the many relationships between these different host responses.

An important link between intrinsic and extrinsic pathways is the TF/factor VIIa complex. This complex is the major component of extrinsic coagulation, but it can also activate factor IX to allow a bypass of the contact phase of intrinsic coagulation. In turn, intrinsic factors XIIa, XIIIf, and IXa, and kallikrein can activate factor VII, which greatly increases the efficiency of extrinsic coagulation. These features give the TF/factor VIIa complex a central role in efficient hemostasis. Extrinsic coagulation and the TF/factor VIIa complex are probably the most important mechanism for in vivo coagulation because bleeding tendencies are not usually associated with factor XII, prekallikrein, and HMWK deficiencies and some factor XI deficiencies in humans and animals.

Some hemostatic reactions initiate pathways that have multiple and sometimes opposite outcomes. Intrinsic pathway factors XIIa, XIIIf, and XIa, and kallikrein not only initiate the formation of fibrin but also initiate fibrinolysis by cleaving plasminogen into plasmin. Factor XIIa not only participates directly in intrinsic coagulation and fibrinolysis but indirectly initiates kinin formation and complement activation by converting prekallikrein to kallikrein. Kallikrein is chemotactic, can directly cleave C5 to C5a, can cleave HMWK to form bradykinin, and can convert plasminogen to plasmin. Plasmin also influences complement activation by cleaving C3 to generate C3a and C3b. Additionally, both kallikrein and plasmin can directly activate factor XII to result in autoamplification of all factor XIIa pathways. Other hemostatic products that influence other host systems include factor Xa, thrombin, and fibrinopeptides, all of which have inflammatory and coagulation functions. These interactions indicate the fine balance within the hemostatic system and the interrelatedness between hemostasis and other host response mechanisms.

### 2.7 DISORDERS OF HEMOSTASIS: HEMORRHAGE AND THROMBOSIS

The purpose of hemostasis is to prevent blood loss following vascular damage, while at the same time maintaining blood in a fluid state so that it flows freely through a normal vasculature. Failure of hemostasis can result in the extravascular loss of blood (hemorrhage) or the inappropriate formation of intravascular thrombus (thrombosis).

#### 2.7.1 HEMORRHAGE

Hemorrhage occurs because of abnormal function or integrity of one or more of the major factors that influence hemostasis—the endothelium and blood vessel, platelets, or coagulation factors.

Abnormalities in blood vessels can result from various inherited or acquired problems. Trauma can physically disrupt a vessel and cause hemorrhage by rhexis (rhexis = breaking forth, bursting). Hemorrhage by rhexis can also occur following vascular erosion by inflammatory reactions or invasive neoplasms. Certain fungi commonly invade and damage blood vessels to cause extensive local hemorrhage (e.g., internal carotid artery erosion secondary to guttural pouch mycosis in horses). More commonly, small defects in otherwise intact blood vessels allow small numbers of erythrocytes to escape by diapedesis (dia = through, pedian = leap). Endotoxemia is a common cause of endothelial injury that results in small widespread hemorrhages (Fig. 2-20). Infectious agents, such as canine adenovirus-1, or chemicals, such as uremic toxins, can also damage endothelium. Similarly, immune complexes can become entrapped between endothelial cells and activate complement and neutrophil influx to result in damage to the endothelium and vessel wall (type III hypersensitivity reaction). Developmental collagen disorders, such as the Ehlers-Danlos syndrome, are sometimes accompanied by hemorrhage. Affected

## Pathologic Basis of Veterinary Disease, 4th Edition

---

blood vessels contain abnormal collagen in their basement membranes and surrounding supportive tissue, resulting in vascular fragility and predisposition to leakage or damage. Similar hemorrhages occur because of the collagen defects in guinea pigs or primates with vitamin C deficiency.

**Fig. 2-20 Hemorrhage, endotoxemia, heart, cow.** Note the epicardial and subepicardial hemorrhages in the fat of the coronary groove (a common site), from injury to the endothelium from endotoxin (component of the cell wall of gram-negative bacteria). The smaller, pinpoint hemorrhages (1 to 2 mm) are petechiae. The larger, blotchy hemorrhages (3 to 5 mm) are ecchymoses. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Decreased platelet numbers (thrombocytopenia) or abnormal platelet function can cause hemorrhage. Thrombocytopenia can result from decreased production, increased destruction, or increased use of platelets. Decreased production generally occurs following megakaryocyte damage or destruction as a result of causes such as radiation injury, estrogen toxicity, cytotoxic drugs, and viral or other infectious diseases (e.g., feline and canine parvoviruses). Increased platelet destruction is often immune-mediated. Autoimmune destruction due to antibody production against platelet membrane components, such as GPIIb and GPIIIa, can occur following immune dysregulation (e.g., systemic lupus erythematosus). Alteration of platelet membranes by drugs or infectious agents may also stimulate immune-mediated destruction or removal of platelets from the circulation. Isoimmune destruction of platelets in neonatal pigs has occurred following ingestion of colostrum-containing antiplatelet antibodies. Viral diseases (e.g., equine infectious anemia and feline immunodeficiency syndrome) and arthropod-borne agents are often associated with platelet destruction and their removal by the spleen. The most common cause of increased platelet use is diffuse endothelial damage or generalized platelet activation, which initiates disseminated intravascular coagulation (DIC). With DIC there is widespread intravascular coagulation and platelet activation, which rapidly results in consumption of platelets and coagulation factors (see thrombosis section). This results in progressive thrombocytopenia and hemorrhage as the syndrome escalates. Another platelet consumption disease that is not accompanied by coagulation is thrombotic thrombocytopenic purpura. In this condition, platelet aggregates form in the microvasculature, possibly due to increased release of proagglutinating substances by normal or damaged endothelium.

Decreased platelet function is usually associated with an inability to adhere or aggregate at a site of vascular injury. Inherited problems of platelet function in humans include deficiency of GPIb on the platelet surface (Bernard-Soulier syndrome), deficient or defective GPIIb and GPIIIa on the platelet surface (Glanzmann's thrombasthenia), and deficient release of platelet granule content ("storage pool disease"). Glanzmann's thrombasthenia is a rare disease that has been reported in Otterhound and Great Pyrenees dogs. In these dogs there is prolonged bleeding and hematoma formation from minor injury and spontaneous epistaxis because of a mutation affecting a  $\text{Ca}^{+2}$ -binding domain of the extracellular portion of GPIIb. Abnormal synthesis or release of platelet granule content has been reported in Simmental cattle, dogs (Spitz, Basset hound, American foxhounds), cats, and fawn-hooded rats. Defective platelet storage of ADP occurs in the Chédiak-Higashi syndrome (Aleutian mink, cattle, Persian cats, killer whales). Acquired platelet inhibition and dysfunction is most often associated with administration of nonsteroidal antiinflammatory drugs, such as aspirin. Aspirin inhibits the cyclooxygenase pathway of arachidonic acid metabolism, thus decreasing thromboxane production to result in reduced platelet aggregation. Platelet function is also inhibited by uremia because of renal failure. Secondary platelet dysfunction can also occur because of deficiencies of factors necessary for normal platelet function. In von Willebrand's disease, or in autoimmune or myeloproliferative disorders in which autoantibodies against von Willebrand's factor are produced, the amount of functional von Willebrand's factor is decreased. This results in decreased platelet adhesion following vascular damage with either subclinical or severe hemorrhage.

83

84

Decreased concentrations or function of coagulation factors can also result in hemorrhage. Inherited deficiencies in coagulation factors have been recognized in many different breeds of dogs and less often other species (Box 2-5). These conditions are characterized by hemorrhage that can range from subclinical to severe. In many cases, the coagulation factor deficiency is recognized because of prolonged bleeding following venipuncture or surgery, but otherwise has minimal significance to the animal. Other inherited deficiencies are characterized by severe episodes of hemorrhage that begin soon after birth.

Acquired defects in coagulation can be caused by decreased production or increased use of coagulation factors. Severe liver disease results in decreased synthesis of most coagulation factors. Production of coagulation factors II, VII, IX, X and proteins C and S is reduced by vitamin K deficiency. Decreased vitamin K production, absorption, or function will reduce conversion of glutamic acid residues into  $\gamma$ -carboxyglutamic acid on these factors. Common substances that competitively inhibit this conversion include dicumarol in moldy sweet clover (*Melilotus alba*), warfarin-containing rodenticides, and sulfaquinoxaline (Fig. 2-21). An inherited deficiency of binding of  $\gamma$ -glutamyl-carboxylase with vitamin K has been reported in British Devon Rex cats. The most common cause of decreased coagulation factors is increased consumption associated with DIC.

The appearance of hemorrhage depends on cause, location, and severity. Hemorrhage within tissue is often characterized based on size. A petechia (pl. petechiae) is a pinpoint (1 to 2 mm) hemorrhage that occurs mainly because of diapedesis associated with minor vascular damage (Fig. 2-20). An ecchymosis (pl. ecchymoses) is a larger (up to 2 to 3 cm in diameter) hemorrhage that occurs with more extensive vascular damage (Fig. 2-22), whereas suffusive hemorrhage affects larger contiguous areas of tissue than the other two types (Fig. 2-23).

84

85

Hemorrhage that occurs into a focal, confined space forms a hematoma. Hematomas are most common in the ears of long-eared dogs or pigs and in the spleen following trauma to the vasculature (Fig. 2-24). The hematoma grows in size until the pressure exerted by the extravascular blood matches that within the injured vessel or the vessel seals internally by hemostasis. Hemorrhage into body cavities results in pooling of coagulated or noncoagulated blood within the cavity and is classified by terms such as hemoperitoneum (blood in the peritoneal cavity), hemothorax (blood in the thoracic cavity), and hemopericardium (blood in the pericardial sac) (Fig. 2-25).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

2.7.1.1	<b>Box 2-5 Examples of Inherited Coagulation Deficiency Disorders</b>
2.7.1.1.1	<b>FACTOR I</b>  Rare, goats and dogs (Bernese mountain dogs, borzoi, Lhasa apso, vizsla, collie). Mild bleeding tendencies in dogs, more severe in goats.
2.7.1.1.2	<b>FACTOR II</b>  Rare, dogs (boxer, Otterhound, English cocker spaniel). Mild bleeding in adults; epistaxis and umbilical cord bleeding in puppies.
2.7.1.1.3	<b>FACTOR VII</b>  Rare, dogs (beagles, also Alaskan malamutes, boxer, bulldog, miniature schnauzer, mix breeds). Mild, more easily bruised.
2.7.1.1.4	<b>FACTOR X</b>  Rare, dogs (cocker spaniels, mix breeds, Jack Russell terrier). Fatal in severely affected dogs, mild to moderate hemorrhage in less severe cases.
2.7.1.1.5	<b>FACTOR XII</b>  Cats and rarely dogs (miniature poodle, standard poodle, German shorthair pointer, Shar-Pei). No bleeding.
2.7.1.1.6	<b>FACTOR XI</b>  Cattle (Holstein and Japanese black) and dogs (Great Pyrenees, English springer spaniel, Kerry blue terrier). Spontaneous hemorrhage is insignificant but can be severe after surgery. Most common hereditary coagulation problem in cattle.
2.7.1.1.7	<b>FACTOR IX (HEMOPHILIA B)</b>  Dogs and cats. Variable bleeding depending on the molecular damage; generally mild in cats and small dogs, more severe in large dogs.
2.7.1.1.8	<b>FACTOR VIII (HEMOPHILIA A)</b>  Dogs, horses, cattle, sheep, and cats. Bleeding can be severe in large dogs and horses; mildly affected animals do not spontaneously bleed.
2.7.1.1.9	<b>VON WILLEBRAND'S DISEASE</b>  Dogs, cats, horses, and pigs. Mild to severe hemorrhage depending on form of molecular damage; epistaxis, mucosal hemorrhage, postsurgical bleeding. Most common inherited canine bleeding disorder.

Suffusive hemorrhage results from severe injury to endothelial cells in the capillary beds. (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The significance of hemorrhage depends mainly on the amount, rate, and location of the blood loss. In most cases, blood loss occurs locally and is quickly stopped by hemostatic processes that seal the damaged vessel. In more severe cases, blood loss continues until local tissue pressure matches intravascular pressure and ends the hemorrhage (such as occurs with hematoma formation). When these mechanisms fail to stop blood loss, significant hemorrhage can occur externally or internally into body cavities. Rapid loss of substantial amounts of blood, such as occurs because of traumatic injury of a large vessel, can lead to hypovolemia, decreased tissue perfusion, and hypovolemic shock (see later discussion in this chapter). In contrast, slow rates of blood loss can be totally or partially compensated for by increased hematopoiesis. Many cases of gastric ulceration and hemorrhage are characterized by persistent but slow rates of blood loss. Some hemorrhages can create pressure that interferes with tissue function. This is most significant in vital organs or in tissue with little room to expand in response to the pressure, such as the brain and heart.

85

86

**Fig. 2-24 Organizing hematoma, spleen, horse.** Trauma to the spleen has caused damage to the splenic red pulp and its vessels, resulting in bleeding into the splenic parenchyma, forming a hematoma. Note that this hematoma is not acute but is several days old, because the blood clot is being degraded. The hematoma is contained by the splenic capsule. (Courtesy Dr. H.B. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 2-25 Hemopericardium, pericardial sac, dog.** Hemorrhage into the pericardial sac has caused its distention. Extensive hemopericardium can interfere with the dilatation and contraction of the ventricles, causing cardiac tamponade. Both coagulated and noncoagulated blood are present in the pericardial sac. (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

### 2.7.2

#### THROMBOSIS

Thrombosis is characterized by the formation of an inappropriate thrombus of fibrin and/or platelets along with other blood elements (thrombus; pl. thrombi) on the wall of a blood or lymphatic vessel or heart (mural thrombus), or free in their lumens (thromboembolus). Major determinants of thrombosis are historically referred to as Virchow's triad and include the endothelium and blood vessels (vascular injury), coagulation factor and platelet activity (coagulability), and the dynamics of blood flow (stasis or turbulence) (Fig. 2-26, Box 2-6).

Changes in the endothelium are the most important factor in thrombosis. Endothelial injury and exposure of tissue factor (TF) and subendothelial components, such as collagen and fibronectin, are potent stimuli for platelet aggregation and coagulation. Causes of injury are widely varied in their severity and cause, and include trauma, vasculitis caused by infection or immunologic reactions, metabolic disorders, neoplasia, and toxins. Additionally, loss of anticoagulant properties of normal endothelium combined with local release of procoagulant substances can result in fibrin formation. Platelets may also adhere to intact endothelium by interacting with altered proteoglycans in the endothelial glycocalyx. Reduced prostacyclin synthesis may also increase platelet adhesion to endothelium.

Abnormal blood flow increases the risk of thrombosis. Reduced blood flow may occur systemically with heart failure or in a local region of congestion caused by vascular obstruction or vascular dilation. Reduced blood flow

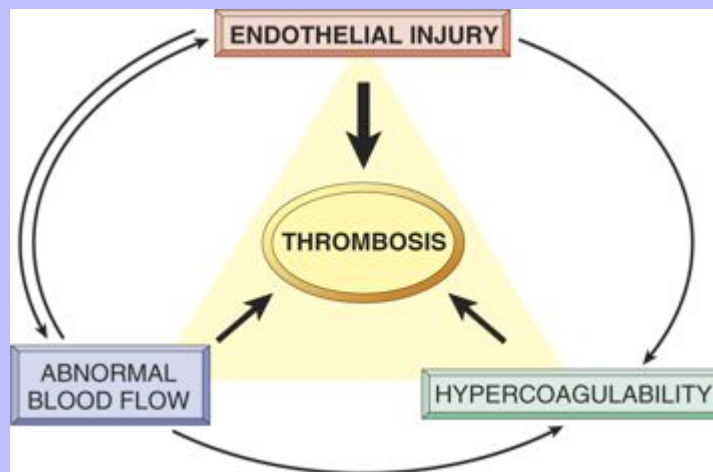

86

87

## Pathologic Basis of Veterinary Disease, 4th Edition

is most important in veins, where the slow flow rate favors accumulation of activated coagulation factors and contact of platelets with the endothelium. Venous thrombosis is common in horses with occlusion of intestinal veins secondary to intestinal torsion. Inactivity can also lead to venous stasis and thrombosis in the limbs, a common problem in humans but not in animals. Dilated heart chambers (e.g., dilatative cardiomyopathy) or dilated vessels (e.g., aneurysms) are also areas where reduced blood flow predisposes to thrombosis.

**Fig. 2-26 Virchow triad in thrombosis.** Endothelial integrity is the single most important factor. Note that injury to endothelial cells can affect local blood flow and/or coagulability; abnormal blood flow (stasis or turbulence) can, in turn, cause endothelial injury. The elements of the triad may act independently or may combine to cause thrombus formation. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 2.7.2.1 Box 2-6 Causes of Thrombosis

#### 2.7.2.1.1 ENDOTHELIAL INJURY

Viruses (e.g., canine adenovirus 1, equine morbillivirus, herpesvirus and arterivirus, ovine orbivirus, bovine and porcine pestivirus)

Bacteria (e.g., *Salmonella typhimurium*, *Mannheimia hemolytica*, *Erysipelothrix rhusiopathiae*, *Hemophilus somnus*)

Fungi (e.g., *Aspergillus*, *Mucor*, *Absidia*, *Rhizopus*)

Nematode parasites (e.g., *Strongylus vulgaris* larvae, *Dirofilaria*, *Spirocerca*, *Aelurostrongylus*, angiostrongylosis)

Immune-mediated vasculitis (e.g., purpura hemorrhagica, feline infectious peritonitis)

## Pathologic Basis of Veterinary Disease, 4th Edition

2.7.2.1.2

Toxins (e.g., endotoxin, *Claviceps*)  
Vitamin E/Selenium deficiency (microangiopathy)  
Local extension of infection (e.g., hepatic abscesses, metritis)  
Disseminated intravascular coagulation (DIC)  
Faulty intravenous injections  
Renal glomerular and cutaneous vasculopathy of greyhounds

### ALTERATIONS IN BLOOD FLOW

Local stasis or reduced flow (e.g., gastric dilation and volvulus, intestinal torsion and volvulus, varicocele, external compression of vessel)  
Cardiac disease (e.g., cardiomyopathy, cardiac hypertrophy)  
Aneurysm (e.g., copper deficiency in pigs, *Strongylus vulgaris*, *Spirocerca lupi*)  
Hypovolemia (e.g., shock, diarrhea, and burns)

2.7.2.1.3

### HYPERCOAGULABILITY

Enhanced platelet activity (e.g., diabetes mellitus, nephrotic syndrome, malignant neoplasia, heartworm disease, uremia)  
Increased clotting factor activation (e.g., nephrotic syndrome, DIC, neoplasia)  
Antithrombin III deficiency (e.g., DIC, hepatic disease, glomerular amyloidosis)  
Metabolic abnormalities (e.g., hyperadrenocorticism, hypothyroidism)  
Glomerulopathies

Turbulent blood flow also enhances the potential for thrombosis. Turbulence disrupts laminar blood flow so the thin layer of plasma that normally separates the endothelium from cellular elements, particularly platelets, is disrupted, and platelets interact more readily with the endothelium. Similarly, turbulence results in mixing of the blood, which provides greater opportunity for interactions between coagulation factors. Turbulence can also physically damage endothelium, creating a strong stimulus for platelet adhesion and coagulation. Turbulence, along with increased risk of thrombosis, is usually greatest in areas where vessels branch, where there is narrowing of the vessel lumen, or at sites of venous or lymphatic valves.

Increased coagulability of blood (hypercoagulability) is another factor that predisposes patients to thrombosis. Hypercoagulability usually reflects an increase or decrease in the concentration of activated hemostatic proteins (e.g., coagulation factors and coagulation or fibrinolytic inhibitors) caused by enhanced activation or decreased degradation of these proteins. Less often, an alteration in hemostatic protein function may influence coagulability. Activity of coagulation and fibrinolytic proteins can increase in certain conditions such as inflammation, stress, surgery, neoplasia, pregnancy, and renal disease (e.g., the nephrotic syndrome). Transient

## Pathologic Basis of Veterinary Disease, 4th Edition

increases in factor I occur with inflammation, stress, and tissue necrosis. Factor I and factor VIII are elevated by trauma, acute illness, surgery, and increased metabolism that accompanies hyperthyroidism. Deficiency of antithrombin III, a major inhibitor of thrombin, occurs relatively often in dogs with the nephrotic syndrome. In this syndrome, ATIII is depleted because of loss through damaged glomeruli. In affected dogs, there is an increased incidence of venous thrombosis and pulmonary embolism. Increased platelet activation (e.g., heartworm disease, nephrotic syndrome, and neoplasia) can also contribute to hypercoagulability of blood.

The appearance of a thrombus depends on its underlying cause, location, and composition (relative proportions of platelets, fibrin, and erythrocytes). Thrombi composed predominantly of platelets and fibrin tend to be pale, whereas those containing many erythrocytes are red. Cardiac and arterial thrombi are usually initiated by endothelial damage. This damage provides a site for firm platelet attachment and subsequent incorporation of fibrin. Rapid blood flow in these arteries and arterioles inhibits passive incorporation of erythrocytes into the thrombus (Fig. 2-27). Cardiac and arterial thrombi are dull, usually firmly attached to the vessel wall and red-gray (pale thrombi) (Fig. 2-28). The thrombus may or may not occlude the vessel lumen, and large thrombi tend to have tails that extend downstream from the point of endothelial attachment. Cardiac and larger arterial thrombi often have a laminated appearance created by rapid blood flow and characterized by alternating layers of platelets, interspersed by fibrin intermixed with erythrocytes and leukocytes (lines of Zahn) (Fig. 2-29).

87

88

**Fig. 2-27 Thrombus (mural), artery.** Thrombus formation is usually initiated by endothelial damage, forming a site of attachment for the thrombus. Growth of the thrombus is downstream, resulting in a tail that is not attached to the vessel wall. Portions of the tail can break off to form thromboemboli. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

**Fig. 2-28 Arterial thrombus, pulmonary artery, dog.** Arterial thrombi are composed primarily of platelets and fibrin because of the rapid flow of blood, which tends to exclude erythrocytes from the thrombus; thus they are usually pale beige to gray (arrow). (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

Venous thrombi often occur in areas of stasis. Because of the slow blood flow and reduced clearance rate of activated clotting factors in these areas, erythrocytes are commonly incorporated into a loose meshwork of fibrin and platelets (Fig. 2-30). Venous thrombi are typically gelatinous, soft, glistening, and dark red (red thrombi) (Fig. 2-31). They are almost always occlusive and molded to the vessel lumen, and often extend for a considerable distance upstream from their point of origin. They commonly have points of attachment to the vessel wall, but these are often very loose and difficult to discern. Venous thrombi are morphologically similar to postmortem clots (see Chapter 1, Fig. 1-24). Compared with venous thrombi, postmortem clots are softer and do not have a point of vascular attachment. In larger vessels or the heart, erythrocytes may settle to the bottom of the clot, leaving a yellow upper layer (chicken fat clot) indicative of postmortem formation. The presence or absence of associated lesions is often a major factor in distinguishing between an antemortem venous thrombus and a postmortem clot.

**Fig. 2-29 Arterial thrombus, lines of Zahn, cranial mesenteric artery, horse.** Cardiac and larger arterial thrombi often have a laminated appearance characterized by alternating layers of platelets (*dark*) and fibrin (*pale*) intermixed with erythrocytes and leukocytes (lines of Zahn). These lines are the result of rapid blood flow in the heart and arteries/arterioles that favors the deposition of fibrin and platelets and the exclusion of erythrocytes from the thrombus. This horse had verminous arteritis (*Strongylus vulgaris* fourth stage larvae) in the affected artery. (Courtesy Dr. P.N. Nation, University of Alberta; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

The significance of a thrombus is determined by its location and its ability to disrupt perfusion in a dependent tissue. Disruption of tissue perfusion is influenced mainly by the size of the thrombus, its rate of formation, and its method of resolution or repair. In general, thrombi that rapidly develop are more detrimental than those that slowly develop. A slowly developing thrombus will create progressive narrowing of the vessel lumen, but the slow rate of development provides opportunity for collateral blood flow to increase into the affected area. Small thrombi are usually less damaging than large thrombi. Small thrombi are more easily removed by thrombolysis with little residual vessel damage or tissue compromise. In contrast, large thrombi substantially narrow the vessel lumen to restrict blood flow, are often occlusive, and are less readily dissolved by thrombolysis (Fig. 2-32). Occlusive thrombi block blood flow either into (occlusive arterial thrombus) or out of (occlusive venous thrombus) an area and often result in ischemia (decreased oxygenation of tissue) or infarction (necrosis of tissue caused by lack of oxygen).

88

89

Fig. 2-30 **Venous thrombus.** Thrombus formation often occurs in areas of slow blood flow or stasis. Venous thrombi are dark red and gelatinous due to large numbers of erythrocytes that are loosely incorporated into the thrombus due to the slow blood flow. Most venous thrombi are occlusive. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

Fig. 2-31 **Venous thrombi, pulmonary vein, lung, horse.** Venous thrombi become molded to the shape of the lumen of the vein and grow upstream from the site of initiation. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

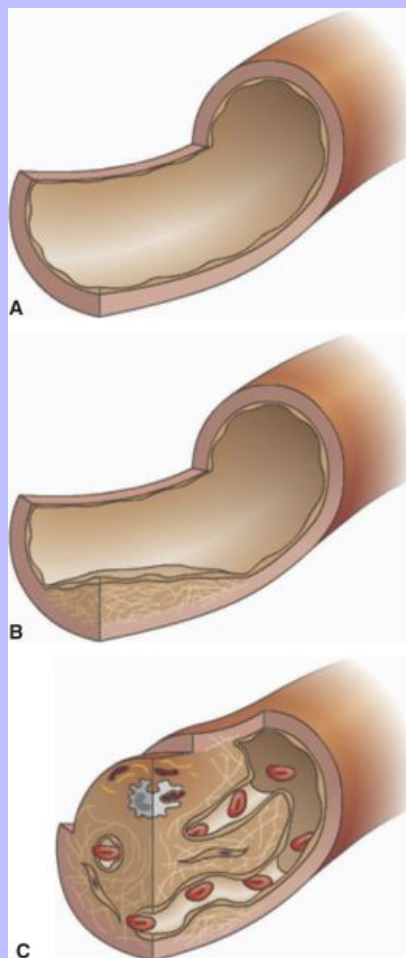

**Fig. 2-32 Large thrombus, pulmonary artery, cow.** Large thrombi are less readily dissolved by thrombolysis and therefore heal by other methods. This thrombus consists of a large coagulum of fibrin that has undergone little to no resolution. H&E stain. (Courtesy Dr. M.A. Miller, College of Veterinary Medicine, University of Missouri; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Under most circumstances and following removal of the injurious stimulus, the well-regulated cascade of events in thrombosis results in the return to normal function of the endothelium and subendothelial collagen (Fig. 2-33, A). However, blood flow through a vessel containing a chronic large or occlusive thrombus can change over time. The thrombus provides an ongoing stimulus for platelet adhesion and coagulation, so thrombus propagation can occur to result in progressive narrowing and possible occlusion of the vessel lumen. A thrombus can also be incorporated into the wall of the vessel by a process similar to that used to replace irreversibly damaged tissue. Products of the aggregated platelets stimulate permanent healing of the damaged area by recruiting fibroblasts to the damaged area. Thrombotic debris is removed by macrophages, and granulation tissue and subsequent fibrosis (organization) occur at the site of the thrombus. Concurrently, there is regrowth of endothelium over the surface of the scar. Although there is a permanent narrowing of the vessel lumen, the regrowth of endothelium over the healed thrombus decreases the stimulus for continued thrombosis (Fig. 2-33, B). In occlusive and some large thrombi, this healing process may be accompanied by invasion and growth of endothelial-lined blood channels through the fibrosed area (recanalization) (Figs. 2-33, C and 2-34). This provides alternate routes for blood flow to reestablish through or around the original thrombus. Although reestablishment of blood flow increases tissue perfusion, the permanent vascular narrowing and altered, more turbulent blood flow at the site of a healed thrombus result in an increased risk for subsequent thrombosis at the site.

89

Fig. 2-33 **Thrombus resolution.** **A**, Small thrombi are removed by thrombolysis, and the blood vessel returns to normal structure and function. **B**, Larger, more persistent thrombi are resolved by removal of thrombotic debris by phagocytes with subsequent granulation tissue formation and fibrosis with regrowth of endothelium over the surface to incorporate the affected area into the vessel wall. **C**, In large mural or occlusive thrombi that are not removed by thrombolysis or phagocytosis of the thrombotic debris, the thrombus is organized by the invasion of fibroblasts and later by the formation of new vascular channels (recanalization), which provides alternate routes for blood flow through and around the site of the original thrombus. (**A**, **B**, and **C**, Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

In some cases, a thrombus or portions of a thrombus can break loose and enter the circulation as an embolus (pl. emboli), a piece of free-floating foreign material within the blood. Thromboemboli (emboli derived from fragments of a thrombus) eventually become lodged in a smaller-sized vessel as the vessel diameter reaches a size that prevents the passage of the embolus, a process called embolization. Venous thromboemboli typically lodge in the pulmonary circulation where they can cause pulmonary infarcts or right-side heart failure. Arterial thromboemboli typically lodge within a smaller artery downstream from the site of the thrombus, often near sites of vascular bifurcation. Arterial emboli frequently result in infarction of dependent tissue, depending on the tissue and nature of its vascular supply. Cardiac thromboemboli usually lodge at the bifurcation of the external iliac arteries with a portion of the thromboembolus entering each iliac vessel to form a saddle thrombus (Fig. 2-35).

**Fig. 2-34 Occlusive mural thrombus, recanalization, cat.** In occlusive and large thrombi, the healing process may occur by fibrosis and the invasion and growth of endothelial-lined vascular channels through the fibrosed area (recanalization). Note the vascular channel, horizontally in the middle of the thrombus. This provides alternate routes for blood flow to reestablish through or around the original thrombus. The permanent vascular narrowing and altered, more turbulent blood flow at the site of a healed thrombus result in an increased risk for subsequent thrombosis at the site. H&E stain. (Courtesy Dr. B.C. Ward, College of Veterinary Medicine, University of Mississippi; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Emboli can also originate from substances other than thrombi. Fat from the bone marrow can be released into the circulation following a fracture of a long bone. Most fat emboli lodge in the pulmonary circulation. Fibrocartilaginous emboli consist of portions of an intervertebral disk, which are released following rupture of a degenerative disk. These can result in occlusion of local vessels and sometimes cause localized spinal cord infarction. Bacteria from inflammatory lesions such as vegetative valvular endocarditis or abscesses can enter the

## Pathologic Basis of Veterinary Disease, 4th Edition

blood to form bacterial emboli. When these lodge within vessels, they may cause infarction and secondary sites of infection. Intravascular parasites, such as heartworms (e.g., <i>Dirofilaria</i> ), or flukes (e.g., schistosomes) can form parasitic emboli. Malignant neoplasms that invade a vessel result in the formation of neoplastic emboli composed of neoplastic cells. Less common sources of emboli include hematopoietic cells from the bone marrow, amniotic fluid, agglutinated erythrocytes, or clumps of other cells, such as hepatocytes, released following tissue trauma. In any case, the significance of these emboli is their potential to occlude a vessel and inhibit blood flow to dependent tissue.	90 91
--	----------

**Fig. 2-35 Saddle thrombus, iliac-aortic bifurcation, cat.** Cardiac thromboemboli usually lodge at the bifurcation of the aorta into the external iliac arteries with a portion of the thromboembolus entering each iliac vessel to form a saddle thrombus. A saddle thrombus is not attached to the wall of the aorta or iliac arteries and is easily removed at necropsy. The thromboembolus is composed of layers of platelets and fibrin in which there are enmeshed erythrocytes. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

A serious manifestation of abnormal coagulation is DIC. This is a severe dyshomeostasis caused by the generation of excess thrombin. There are many causes, including diffuse vascular damage (e.g., trauma, vasculitis, and burns), which results in exposure of blood to TF. Intravascular generation of TF by endothelial cells and monocytes can also occur in response to bacteremia, other systemic infections, or any other stimuli that activate the release of inflammatory mediators. The result is TF-induced activation of extrinsic coagulation to produce thrombin. Thrombin causes platelet aggregation and activation of coagulation factors V, VIII, and I to form fibrin, resulting in widespread microvascular clots. Concurrently the high levels of thrombin stimulate clot dissolution by binding to thrombomodulin to activate protein C, by converting plasminogen into plasmin, and by binding to ATIII to become inactivated. The widespread nature of the coagulation response results in the consumption of these and other factors, resulting in widespread hemorrhages. This combination of microthrombosis with concurrent or rapidly sequential hemorrhage represents one of the most profound and dramatic examples of dyshomeostasis in animals.

### 2.8 NORMAL BLOOD FLOW, DISTRIBUTION, AND PERFUSION

The heart provides the driving pressure for blood distribution. Baroreceptors in the carotid sinus and aortic arch signal the cardiovascular control center in the medulla to balance sympathetic and parasympathetic output to maintain appropriate blood pressure. Left atrial volume receptors and hypothalamic osmoreceptors also help regulate pressure by altering water volume and sodium balance. Sodium concentration is an important contributor to blood volume, osmolality, and pressure, and is controlled by the renin-angiotensin-aldosterone system. Secretion of ADH by the hypothalamus in response to a water deficit increases renal tubular reabsorption of water to help maintain blood volume.

Distribution of blood within the circulatory system is highly variable. Organs that alter or recondition blood (e.g., lungs, gastrointestinal tract, kidney, and liver) receive substantially greater blood flow than is required for their metabolic needs. Oxygen and CO<sub>2</sub> are exchanged in the lungs, nutrients are obtained from the gastrointestinal tract and processed by the liver, wastes are removed and electrolytes are balanced by the kidneys, heat is dissipated in the skin, and regulatory hormones enter from endocrine tissues. Systemic neural and hormonal influences can cause general changes in blood distribution. Blood vessel  $\beta_2$  receptors, most abundant in cardiac and skeletal muscle, cause vasodilation and increased flow when stimulated by epinephrine. In contrast, vessel  $\alpha$ -receptors, notably absent in the brain, induce vasoconstriction and reduced flow in most organs upon stimulation with norepinephrine. Local intrinsic controls alter arteriolar radius to adjust the blood flow to a tissue based on that tissue's metabolic needs. These local controls generally override any central controls to maintain adequate blood flow to support normal cell function. At rest, more than 60% of the circulating blood volume is in the veins, providing a storage pool that can be quickly returned to the heart during periods of increased tissue need. In contrast, most capillary beds are closed at any given time; blood flows through only about 10% of the total capillaries of resting skeletal muscle. The orchestration of central pressure, blood composition, and blood distribution is critical to meet the varying perfusion needs of all the cells in the body despite constantly changing conditions.

91

### 2.9 ALTERATIONS IN BLOOD FLOW AND PERFUSION

92

#### 2.9.1 INCREASED BLOOD FLOW

Hyperemia is an active engorgement of vascular beds with a normal or decreased outflow of blood. It occurs because of increased metabolic activity of tissue that results in localized increased concentrations of CO<sub>2</sub>, acid, and other metabolites. These cause a local stimulus for vasodilation and increased flow (hyperemia). Hyperemia can occur as a physiological mechanism within the skin to dissipate heat. It also occurs because of increased need, such as increased blood flow to the gastrointestinal tract after a meal. Hyperemia is also one of the first vascular changes that occur in response to an inflammatory stimulus (Fig. 2-36). Neurogenic reflexes and release of vasoactive substances, such as histamine and prostaglandins, mediate the change to promote delivery of inflammatory mediators to the site. Tissues with hyperemic vessels are bright red and warm, and there is engorgement of the arterioles and capillaries.

**Fig. 2-36 Hyperemia versus congestion.** In both cases, there is an increased volume and pressure of blood in a given tissue with associated capillary dilation and a potential for fluid extravasation. In hyperemia there is increased inflow leading to engorgement with oxygenated blood. In congestion, diminished outflow leads to a capillary bed swollen with deoxygenated venous blood resulting in cyanosis. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 2.9.2 DECREASED BLOOD FLOW

Congestion is the passive engorgement of a vascular bed generally caused by a decreased outflow with a normal or increased inflow of blood (Fig. 2-36). Passive congestion can occur acutely (acute passive congestion) or chronically (chronic passive congestion). Acute passive congestion occurs following euthanasia or in acute heart

failure (cardiac arrhythmias) in dependent organs, such as the lung and liver (Fig. 2-37), or in organs in which relaxation of smooth muscle from barbiturate euthanasia results in dilation of the vasculature and vascular sinusoids, such as in the spleen. Most passive congestion occurs and is recognized clinically as chronic passive congestion. It can occur locally because of the obstruction of venous outflow caused by a neoplastic or inflammatory mass, displacement of an organ, or fibrosis resulting from healed injury. Generalized passive congestion occurs because of decreased passage of blood either through the heart or the lungs. This is most often caused by heart failure or conditions (e.g., pulmonary fibrosis) that inhibit the flow of blood through the lungs. Right sided heart failure causes portal vein and hepatic congestion (Fig. 2-38). Left sided heart failure results in pulmonary congestion (Fig. 2-39). Chronically, there may be fibrosis caused by the hypoxia and cell injury that accompanies congestion (e.g., chronic hepatic congestion). Congested tissues are dark red, swollen (edema), and cooler than normal. The microvasculature is engorged with blood, and there is often surrounding edema and sometimes hemorrhage caused by diapedesis.

92

93

**Fig. 2-37 Acute passive congestion, liver, dog.** The liver is enlarged and dark red. Acute passive congestion occurs in the vascular system and dependent organs (heart, lungs, portal system) when there is a sudden interruption of the return of blood to the heart as occurs in heart failure resulting from arrhythmias and following euthanasia. (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

**Fig. 2-38 Chronic passive congestion (nutmeg liver), liver, cut surface, dog.**

The cut surface has a repeating pattern of red and tan mottling (an accentuated lobular pattern). Chronic passive congestion leads to persistent hypoxia in centrilobular areas and atrophy, degeneration, and/or eventually necrosis of centrilobular hepatocytes. The red areas are dilated central veins and adjacent areas of sinusoidal dilation and congestion due to centrilobular hepatic necrosis. The tan areas are normal, uncongested parenchyma. (*Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.*)

**Fig. 2-39 Chronic passive congestion, lung, dog.** The lungs are moderately firm and yellow-brown because of alveolar macrophages containing hemosiderin. Inflammatory mediators produced by these macrophages also induce fibroplasia, and thus long-term there is extensive formation of interstitial collagen. This collagen is the reason the lungs fail to collapse following loss of negative pressure in the pleural cavity when the diaphragm is incised at necropsy. (*Courtesy College of Veterinary Medicine, University of Illinois.*)

### 2.9.3

#### DECREASED TISSUE PERFUSION

Reduced blood flow to an area is usually caused by a local obstruction of a vessel, local congestion, or decreased cardiac output. Local obstruction results in either reduced blood flow into an area or inadequate blood flow out of an area. Ischemia occurs when the perfusion of tissue in the affected area becomes inadequate to meet the metabolic needs of the tissue. Ischemia caused by arterial disease is most commonly due to incomplete luminal blockage by a thrombus or embolus. The result is a decreased flow of oxygenated blood into the area. Arteriolar vasoconstriction, if prolonged, can also result in ischemia. Ischemia due to venous lesions can be caused by intraluminal obstruction, such as a venous thrombus. However, external pressure that occludes the vein, such as inflammatory or neoplastic masses, is a common cause. Venous obstruction leads to congestion characterized by slowing and stagnation of blood flow, with loss of tissue oxygenation, local increased hydrostatic pressure, and leakage of fluid into the interstitium (edema). Increased interstitial pressure may partially inhibit arterial inflow into the area to compound the problem. Capillaries can also become occluded by thrombi or external pressure. The severity of ischemia is determined by the local vascular anatomy and degree of anastomoses and collateral

## Pathologic Basis of Veterinary Disease, 4th Edition

---

circulation, the number of microcirculatory vessels and degree of resistance of the arteriole supplying the capillaries, the extent of the decreased perfusion, the rate at which the occlusion occurred, and the metabolic needs of the tissue. Ischemia can be tolerated to different levels by different tissue. The brain and heart are most susceptible because of a high need for O<sub>2</sub> and nutrients combined with poor collateral circulation. In contrast, organs that recondition blood (e.g., lungs, gastrointestinal tract, kidneys, and skin) can tolerate substantial reductions in flow because they already receive more blood than necessary for their metabolic needs. Other tissues receive blood based on their immediate needs (e.g., skeletal muscle during physical activity). Rapid and complete occlusion that affects large areas of tissue is generally more severe because collateral circulation may not be able to reestablish flow to certain areas quickly enough to prevent tissue necrosis.

93

---

In tissue in which there has been a return of blood flow after brief ischemia, the tissue often returns to normal.

94

The ATP of ischemic tissue is degraded to adenosine, a potent vasodilator, which relieves the ischemia and allows ATP production to resume. However, after prolonged ischemia, the return of blood flow can result in a variety of detrimental effects. Reflow results in fluid loss to the interstitium, resulting in high tissue pressure, which compresses veins and inhibits local venous return. The congested capillaries hemorrhage, TF is released, and vessels are occluded by thrombi. In ischemic cells, a breakdown product of ATP is hypoxanthine. In the absence of oxygen, this is nonreactive. However, upon the return of oxygen, xanthine oxidase converts hypoxanthine into urates, hydrogen peroxide, and superoxide anions. Subsequent reaction of superoxide results in the formation of additional reactive oxygen species, such as hydroxyl radicals. Collectively, these oxygen free radicals formed during reperfusion can create damage in addition to that caused by ischemia and energy depletion of the cell.

An infarct is a local area of peracute ischemia that undergoes coagulative necrosis. Infarction is caused by the same events that result in ischemia and is most commonly secondary to thrombosis or thromboembolism. The characteristics of an infarct are variable based on the type and size of vessel that was occluded (artery or vein), the duration of the occlusion, the tissue in which it occurs, and the prior perfusion and vitality of the tissue. Complete arterial blockage usually results in immediate infarction (Fig. 2-40). In contrast, when venous obstruction occurs, such as due to torsions or displacements of the bowel, there is extensive congestion and edema of the affected bowel that precedes and promotes infarction. Concurrent disease, decreased cardiovascular function, anemia, or decreased tissue vitality will increase the likelihood of localized areas of ischemia progressing to infarction. In tissue with a single blood supply and minimal anastomoses (e.g., brain, heart, kidney, and spleen), occlusion of nearly any sized vessel typically results in infarction of the dependent tissue (Fig. 2-41). In tissue with parallel blood supplies that have numerous anastomoses (e.g., skeletal muscle and gastrointestinal tract), occlusion is less serious unless it occurs in a large vessel. Tissues with dual blood supplies (e.g., liver and lung) are not commonly susceptible to infarction unless concurrent underlying disease is present that compromises the overall blood supply.

**Fig. 2-40 Infarction due to arterial obstruction.** Arterial obstruction results in loss of blood flow to downstream tissue, resulting in abrupt coagulative necrosis. The amount of necrosis is dependent on factors such as the type and prior health of the tissue affected, its metabolic rate (neurons versus myocytes and fibroblasts), and amount of collateral circulation or alternative blood supply. 1, Normal arterial flow; 2, arterial flow obstructed by an arterial thrombus. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

Most infarcts are dark red soon after their occurrence because of hemorrhage from damaged vessels in the infarcted area, and backflow of blood into the area from surrounding vessels (Fig. 2-41). As cells undergo necrosis, there is swelling of the affected area, which can force blood out of the infarcted region, giving it a pale appearance (Fig. 2-42). Additionally, hemolysis of erythrocytes and degradation and diffusion of hemoglobin give the infarct a progressively paler appearance. This change in color can occur within 1 to 5 days depending on the tissue and extent of the infarction. Certain types of tissue that have a loose (spongy) consistency, such as the lungs and storage-type spleens (e.g., dogs and pigs), usually remain red because the interstitial areas are expandable and necrosis-induced pressure does not build up to force blood out of the infarcted region (Figs. 2-43 and 2-44). Parenchymal tissues with a less expansible interstitium (e.g., kidney) generally become pale over time because of the pressure that forces blood from the necrotic area. Inflammation occurs at the periphery of the dead tissue so that leukocytes, then macrophages, enter the area to clear the necrotic debris, and subsequently neovascularization and granulation occur to replace the necrotic region with fibrous tissue. This process can occur over a period of weeks or months depending on the extent of the damage. In contrast to the coagulative necrosis caused by infarction in most tissue, infarction in the brain and nervous tissue is characterized by liquefactive necrosis. Subsequently there is glial cell removal of damaged tissue and astrocytic production of glial fibers (astrogliosis) to replace the affected area.

94

95

Fig. 2-41 **Acute hemorrhagic infarct, kidney, dog.** There is a focal wedge-shaped hemorrhagic area of cortical necrosis. The capsular surface of the infarct bulges above that of the adjacent normal kidney, indicating acute cell swelling and hemorrhage. (*Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

Fig. 2-42 **Acute pale infarcts, kidney, rabbit.** Multiple, pale white to tan pyramidal-shaped infarcts extend from the renal cortex to the medulla. The infarcts bulge above the capsular surface (*center top*), indicative of acute cell swelling. The glistening areas on the right are highlights from the photographic lamps. ## Pathologic Basis of Veterinary Disease, 4th Edition

### 2.10 SHOCK

Shock (cardiovascular collapse) is a circulatory dyshomeostasis associated with loss of circulating blood volume, reduced cardiac output, and/or inappropriate peripheral vascular resistance. Although causes can be diverse (e.g., severe hemorrhage or diarrhea, burns, tissue trauma, endotoxemia), the underlying events of shock are relatively stereotyped. Hypotension results in impaired tissue perfusion and cellular hypoxia and a shift to anaerobic metabolism by cells, cellular degeneration, and death (Fig. 2-45). Although the cellular effects of hypoperfusion are initially reversible, persistence of shock results in irreversible cell and tissue injury. Shock is rapidly progressive and life threatening when compensatory responses are inadequate. Shock can be classified into three different types based on the fundamental underlying problem: (1) cardiogenic, (2) hypovolemic, and (3) blood maldistribution.

95

96

Shock attributed to blood maldistribution can be further divided into septic shock, anaphylactic shock, and neurogenic shock.

**Fig. 2-43 Infarction due to venous obstruction.** Venous obstruction results in stagnation of blood flow and reduction or loss of venous return. There is progressive ischemia and ultimately coagulative necrosis of the tissue upstream of the site of vessel obstruction. The amount of necrosis is dependent on factors such as the type and prior health of the tissue affected, metabolic rate, and amount of collateral circulation or alternative blood supply. 1, Venous return to a larger vein (note the valve) obstructed by a mass (*M*); 2, normal venous return to a larger vein. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

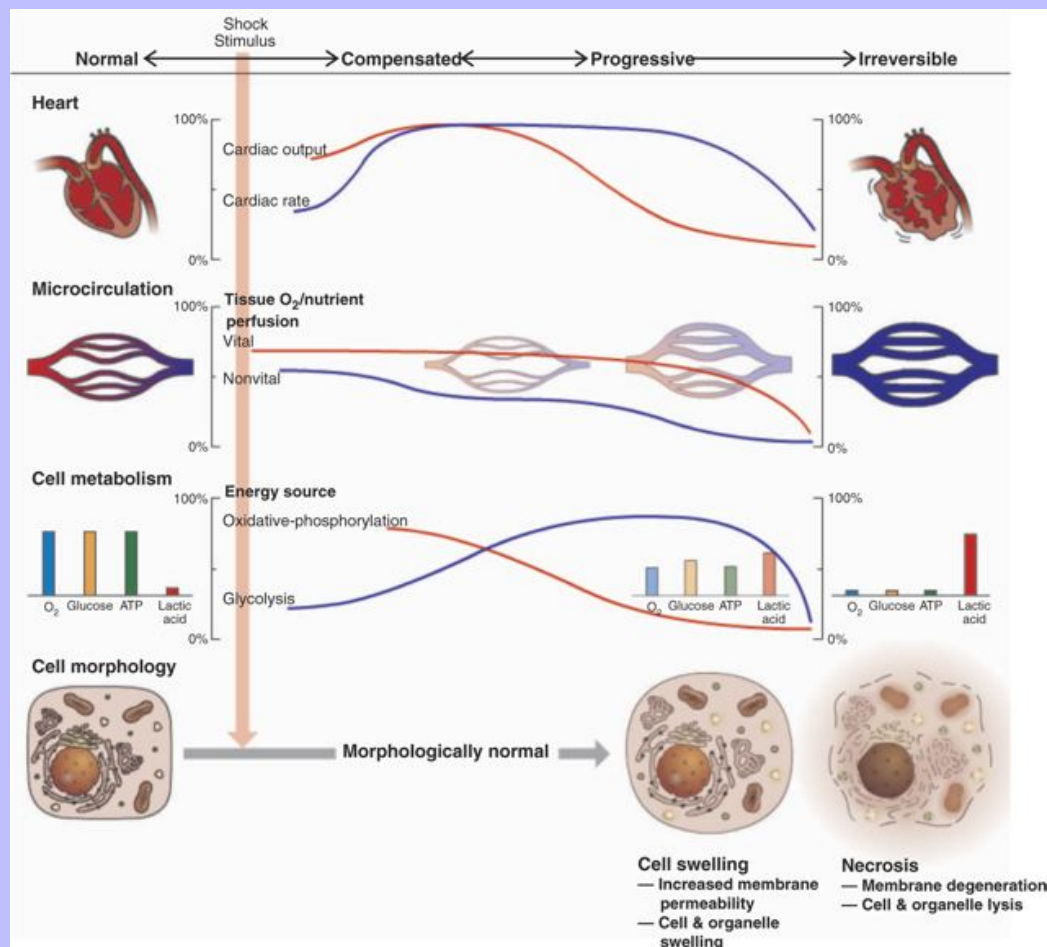

Fig. 2-44 **Venous infarction, small intestinal volvulus, pig.** Note the intensely congested loops of small intestine undergoing early venous infarction. The veins have been compressed by a volvulus that has compressed the veins but not the arteries, thus preventing the venous return. If the volvulus had rotated further, it would also have compressed the arteries. (Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

**Fig. 2-45 Shock.** In hypovolemic shock, there is initially compensation characterized by increased cardiac rate and output, vasoconstriction of nonessential vascular beds, and predominantly oxidative metabolism by morphologically normal cells. With progression, cardiac output falls as peripheral vasodilation occurs and cell metabolism shifts to glycolysis with progressive morphological changes in cells. (Courtesy Dr. D.A. Mosier and L. Schooley, College of Veterinary Medicine, Kansas State University.)

### 2.10.1 CARDIOGENIC SHOCK

Cardiogenic shock results from failure of the heart to adequately pump blood. Cardiac failure can occur due to myocardial infarction, ventricular tachycardia, fibrillation or other arrhythmias, dilatative or hypertrophic cardiomyopathy, obstruction of blood flow from the heart (e.g., pulmonary embolism and pulmonary or aortic stenosis), or other cardiac dysfunctions. In all cases, there is a decrease in both stroke volume and cardiac output.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Major compensatory mechanisms (e.g., sympathetic stimulation of the heart), which increase heart contractility, stroke volume, total cardiac output, and heart rate, are only variably successful depending on the nature of the cardiac damage and the ability of the damaged heart to respond. Unsuccessful compensation leads to stagnation of blood and progressive tissue hypoperfusion.

96

### 2.10.2 HYPOVOLEMIC SHOCK

97

Hypovolemic shock arises from reduced circulating blood volume due to blood loss caused by hemorrhage, or due to fluid loss secondary to vomiting, diarrhea, or burns. Reduced circulating blood volume leads to decreased vascular pressure and tissue hypoperfusion. Immediate compensatory mechanisms (e.g., peripheral vasoconstriction and fluid movement into the plasma) act to increase vascular pressure and maintain blood flow to critical tissues, such as the heart, brain, and kidney. Increased pressure provides an adequate driving force upon which local mechanisms can draw on to increase blood flow based on their needs. When the insult is mild, compensation is generally successful and the animal returns to homeostasis. Loss of about 10% of blood volume can occur without a decrease in blood pressure or cardiac output. However, if greater volumes are lost, adequate pressure and perfusion can not be maintained and there is insufficient blood flow to meet the needs of the tissues. When blood loss approaches 35% to 45%, blood pressure and cardiac output can fall dramatically.

### 2.10.3 BLOOD MALDISTRIBUTION

Blood maldistribution is characterized by decreased peripheral vascular resistance and pooling of blood in peripheral tissues. This is caused by neural or cytokine-induced vasodilation that can result from situations such as trauma, emotional stress, systemic hypersensitivity to allergens, or endotoxemia. Systemic vasodilation results in a dramatically increased microvascular area, and although the blood volume is normal, the effective circulating blood volume is decreased. Unless compensatory mechanisms can override the stimulus for vasodilation, there is pooling and stagnation of blood with subsequent tissue hypoperfusion. The three major types of shock due to blood maldistribution are anaphylactic, neurogenic, and septic shock.

Anaphylactic shock is a generalized type I hypersensitivity. Common causes include exposure to insect or plant allergens, drugs, or vaccines. The interaction of the inciting substance with immunoglobulin E bound to mast cells results in widespread mast cell degranulation and the release of histamine and other vasoactive mediators. Subsequently, there is systemic vasodilation and increased vascular permeability, causing hypotension and tissue hypoperfusion.

Neurogenic shock may be induced by trauma, particularly trauma to the nervous system; electrocution such as by lightning strike; fear; or emotional stress. In contrast to anaphylactic and endotoxic shock, cytokine release is not a major factor in the initial peripheral vasodilation. Instead, there are autonomic discharges that result in peripheral vasodilation, followed by venous pooling of blood and tissue hypoperfusion.

Septic shock is the most common type of shock associated with blood maldistribution. In septic shock, peripheral vasodilation is caused by components of bacteria or fungi that induce the release of excessive amounts of vascular and inflammatory mediators. The most common cause of septic shock is endotoxin, a lipopolysaccharide (LPS) complex within the cell wall of gram-negative bacteria. Less often, peptidoglycans and lipoteichoic acids of gram-positive organisms initiate shock. Local release of LPS from degenerating bacteria is a potent stimulus for many of the host responses that are necessary to respond to the infectious agent. LPS often gains entry from microflora of the bowel, entering the circulation into the reticuloendothelial system, then accumulating in the liver, spleen, alveoli, and leukocytes. LPS activates cells (mainly endothelium and leukocytes) through a series of reactions involving LPS-binding protein (an acute phase protein), CD14 (a cell

## Pathologic Basis of Veterinary Disease, 4th Edition

membrane protein and soluble plasma protein) and Toll-like receptor 4 (TLR4, a signal-transducing protein). Endothelial activation by LPS inhibits production of anticoagulant substances (e.g., TFPI and thrombomodulin). Activation of monocytes and macrophages by LPS induces the direct or indirect release of TNF and IL-1 and other cytokines (e.g., IL-6, IL-8, chemokines). LPS directly activates factor XII to initiate intrinsic coagulation and other factor XIIa-related pathways (kinins, fibrinolysis, complement). LPS can also directly activate the complement cascade pathway to generate the anaphylatoxins C3a and C5a. Although these events are important for enhancing the inflammatory response to control localized infections associated with relatively low concentrations of LPS, they can be detrimental if the response becomes more pronounced. This may occur with overwhelming infections by bacteria (generating large concentrations of LPS), or when prolonged intestinal ischemia due to other types of shock results in breakdown of the mucosal integrity and leakage of bacteria and toxins into the blood. These higher concentrations of LPS induce even more production of TNF, IL-1, and other cytokines, and the secondary effects of these cytokines become more prominent. TNF and IL-1 induce TF expression and endothelial activation of extrinsic coagulation and enhance the expression of endothelial leukocyte adhesion molecules. IL-1 also stimulates the release of platelet activating factor (PAF) and tissue plasminogen activator inhibitor (TPAI) to enhance platelet aggregation and coagulation. PAF released from leukocytes, platelets, and endothelium can cause platelet aggregation and thrombosis, increased vascular permeability, and, similar to TNF and IL-1, stimulation of arachidonic acid metabolite production (particularly PGI<sub>2</sub> and thromboxane). TNF and IL-1 induce nitric oxide production, which also contributes to vasodilation and hypotension. Neutrophils become activated by TNF and IL-1 to enhance their adhesion to endothelium, which further interferes with blood flow through the microvasculature. The end result of the activation of these myriad vascular, proinflammatory, and procoagulant alterations is the profound systemic vasodilation, hypotension, and tissue hypoperfusion characteristic of septic shock.

97

98

### 2.10.4 STAGES AND PROGRESSION OF SHOCK

Regardless of the underlying cause, shock generally progresses through three different stages: (1) a nonprogressive stage, (2) a progressive stage, and (3) an irreversible stage.

Nonprogressive shock is characterized by compensatory mechanisms that counteract reduced functional circulating blood volume and decreased vascular pressure. Baroreceptors respond to decreased pressure by increasing medullary sympathetic nervous output and epinephrine/norepinephrine release, which increases cardiac output and causes arteriolar vasoconstriction (increased peripheral resistance) in most tissues in an attempt to raise vascular pressure. Notable exceptions are critical tissues, such as the heart, brain, and kidney, to which the blood flow is preserved. Left atrial volume receptors and hypothalamic osmoreceptors help regulate pressure by altering water and sodium balance. Reduced plasma volume stimulates ADH release and water retention, and activates angiotensin II production by the renin-angiotensin system to result in aldosterone release and sodium retention. ADH and angiotensin II are also vasoconstrictors and help contribute to increased peripheral resistance. Vasoconstriction also results from endothelial release of endothelin, cold, increased O<sub>2</sub>, or decreased CO<sub>2</sub>. Decreased microvascular pressure results in a shift in fluid movement from the interstitium into the plasma to also help increase blood volume. The results of these and other responses are increased heart rate and cardiac output, and increased vascular pressure. This provides an adequate driving force upon which local mechanisms can draw on to increase blood flow based on their needs. When the insult is mild, compensation is generally successful and the animal returns to homeostasis.

In the case of severe or prolonged hypovolemia or cardiac damage that inhibits the ability of the heart to increase output, compensatory mechanisms are inadequate and shock enters the progressive stage. In this stage there is blood pooling, tissue hypoperfusion, and progressive cell injury. Cellular metabolism becomes less efficient and shifts from aerobic to anaerobic with pyruvate converted to lactate without entering the Krebs cycle. The

## Pathologic Basis of Veterinary Disease, 4th Edition

---

deficient production of ATP and overproduction of lactic acid inhibits normal cell functions and results in cellular and systemic acidosis. Metabolic products (e.g., adenosine and potassium), increased local osmolarity, local hypoxia, and increased CO<sub>2</sub> eventually result in arteriolar relaxation and dilation. In the case of septic shock, these events exacerbate preexisting cytokine- and mediator-induced vasodilation of the microvasculature. In hypovolemic and cardiogenic shock, the decreased vascular resistance initiates pooling and stagnation of blood within previously closed vascular beds. Widespread arteriolar dilation due to local influences overrides systemic controls and dramatically contributes to further decreases in vascular plasma volume and pressure. When oxygen and energy stores of the cell are depleted, membrane transport mechanisms are impaired, lysosomal enzymes are released, structural integrity is lost, and cell necrosis occurs. In addition to the detrimental metabolic effects of deficient oxygenation, cell and tissue injury occur in response to the dramatic accumulation of mediators that is characteristic of progressive shock regardless of its underlying cause. These include histamine, kinins, PAF, complement fragments, and a wide variety of cytokines (e.g., TNF, IL-1, IL-8). These mediators are associated with inappropriate systemic inflammation and systemic activation of complement, coagulation, fibrinolysis, and kinin pathways.

The exact point where shock enters the irreversible stage is not clear. At the cellular level, metabolic acidosis that results from anaerobic metabolism inhibits enzyme systems needed for energy production. Decreased metabolic efficiency allows vasodilatory substances to accumulate in the ischemic cells and tissues. Once these local products and reflexes override centrally mediated vasoconstriction to produce vasodilation, it is unlikely that shock will be reversed. The fall in peripheral resistance due to widespread peripheral vasodilation decreases vascular pressure even more. Irreversibility is generally assured when shock progresses into the syndrome of multiple organ dysfunction. As each organ system fails, particularly the lung, liver, intestine, kidney, and heart, there is a reduction in the metabolic support each system provides to the others. Vicious cycles occur in which the failing function of one organ or tissue contributes to the failure of another (e.g., decreased cardiac output causes renal and pancreatic ischemia; electrolyte imbalances caused by renal ischemia then result in cardiac arrhythmias and myocardial depressant factor released by the ischemic pancreas contribute to even greater reductions in cardiac output). The end point of irreversible shock is often manifested as DIC, the profound and paradoxical dysfunction of hemostasis.

98

2.10.5

### CLINICAL AND MORPHOLOGICAL FEATURES OF SHOCK

99

Clinical features of shock are rapidly progressive and include hypotension, weak pulse, tachycardia, hyperventilation with pulmonary rales, reduced urine output, and hypothermia. Organ and system failure occur in later stages, each manifesting with signs specific to that organ or tissue.

The lesions of shock are variable and depend on the nature and severity of the initiating stimulus, and the stage of progression of shock. Characteristically there are vascular changes accompanied by cell degeneration and necrosis. Generalized congestion and pooling of blood are present in most cases, unless there has been substantial blood loss. Edema, hemorrhage (petechial and ecchymotic), and thrombosis may be present as reflections of the vascular deterioration that accompanies shock. Thrombosis and platelet plugging of capillaries can be prominent in septic shock. Vascular abnormalities are most obvious in those cases that progress to DIC. Cell degeneration and necrosis is most prominent in those cells that are most susceptible to hypoxia, such as neurons and cardiac myocytes, and cells that do not obtain adequate preferential blood flow during shock. Hepatocytes, renal tubular epithelium, adrenal cortical epithelium, and gastrointestinal epithelium are often affected. With the exception of neuronal and myocyte loss, virtually all of these tissue changes can revert to normal if the animal survives. Specific changes may include severe pulmonary congestion, edema, and hemorrhage with alveolar epithelial necrosis, fibrin exudation, and hyaline membrane formation. Passive congestion and centrilobular hepatic necrosis, as well as renal tubular necrosis, are often present in these

## Pathologic Basis of Veterinary Disease, 4th Edition

metabolically important organs. Intestinal congestion, edema, and hemorrhage with mucosal necrosis may occur. In the heart there is myofibril coagulation due to hypercontraction of sarcomeres. This is most likely a response to high sarcoplasmic calcium levels due to lack of energy and membrane damage. Cerebral edema, and in some cases cerebrocortical laminar necrosis, as a result of cerebral ischemia may be present.

## 3 Chapter 3 Acute Inflammation

MARK R. ACKERMANN

### 3.1 INTRODUCTION

When cells are injured by stimuli such as mechanical trauma, tissue necrosis, cancerous cells, or infectious microbes, as discussed in [Chapter 1](#), these stimuli can trigger a well-organized cascade of fluidic and cellular changes within living vascularized tissue called acute inflammation ([Fig. 3-1](#)). These changes result in the accumulation of fluid, electrolytes, and plasma proteins as well as leukocytes in extravascular tissue and are recognized clinically by redness, heat, swelling, pain, and loss of function of the affected tissue. Inflammation is often a protective mechanism whose biologic purpose is to dilute, isolate, and eliminate the cause of injury and to repair tissue damage resulting from the injury. Without inflammation, animals would not survive their daily interactions with environmental microbes, foreign materials, and trauma, and with some degenerate, senescent, and neoplastic cells.

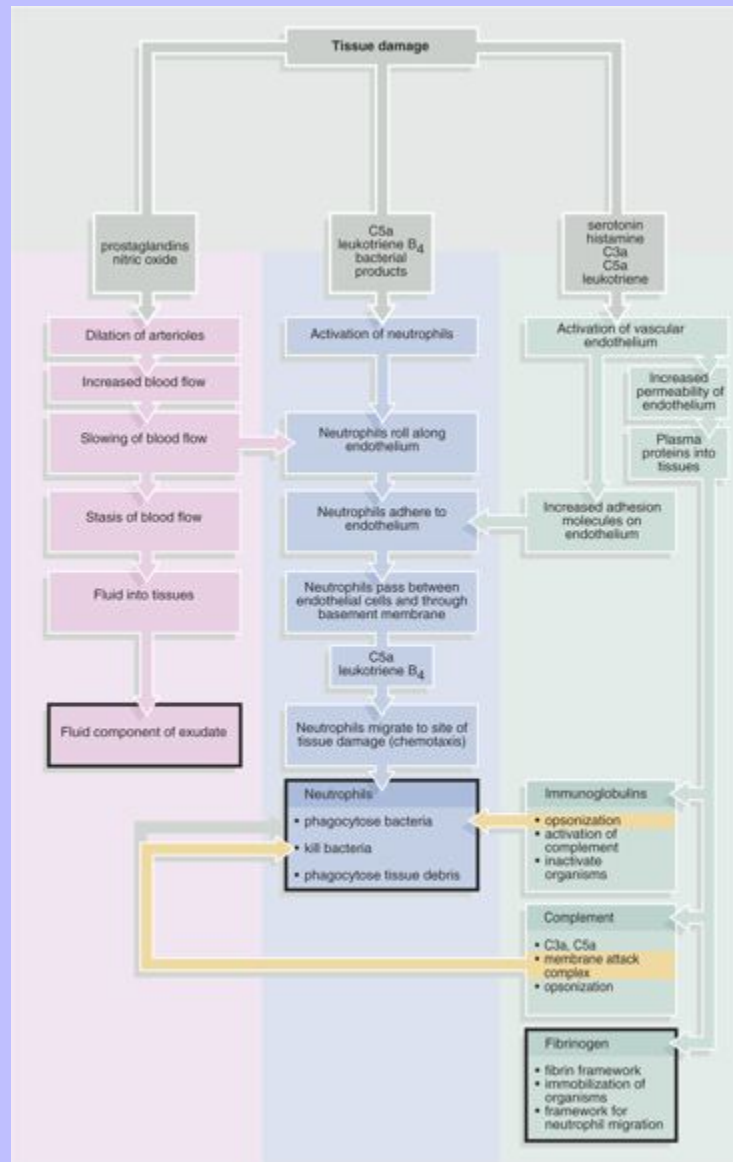

Our understanding of inflammation has evolved over the last 5000 years of recorded history ([Table 3-1](#)). Clinical signs attributable to inflammation were first described in Egypt in 3000 BC. Celcus, a Roman writer (de Medicina Celcus, 25 BC to 50 AD), was the first individual to describe the four cardinal signs of inflammation (redness, heat, swelling, and pain) that are commonly used today to diagnose inflammation in medicine. In the mid 1800s, Rudolf Virchow, the founder of modern pathology, added the fifth cardinal sign of inflammation, loss of function. In addition to his numerous contributions to cellular pathology, Dr. Virchow, by the age of 25, had discovered fibrinogen, described the processes of leukocytosis, and later characterized pus and necrosis. In 1859, his book titled *Cell Pathology* became the basis for all microscopic study of disease. Phagocytosis by macrophages, an important component of inflammation and immunologic responses, was first described by Elie Metchnikoff in 1883. In 1908 he was awarded the Nobel Prize in Medicine for these studies. Finally, the first experiment to demonstrate the role of a chemical mediator (histamine) in inducing vascular changes (flare and wheal reactions) was conducted by Sir Thomas Lewis in 1927. Work of these pioneers, as well as additional experimental studies conducted during the past century, has provided: (1) an in-depth and clearer understanding of inflammation and (2) the foundation for development of therapeutic compounds to treat undesirable effects of inflammatory responses. In fact, such treatments are so widely used and commonplace in veterinary medicine today, that the contributions and discoveries of these scientists are often taken for granted.

Acute inflammation, a provoked response, is the progressive reaction of vascularized living tissue to injury over time. This process is usually a well-ordered cascade mediated by chemoattractants, vasoactive molecules, proinflammatory and inflammatory cytokines and their receptors, and antimicrobial or cytotoxic molecules. Acute inflammation has a short duration ranging from a few hours to a few days and its principal characteristics are microvascular exudation of electrolytes, fluid, and plasma proteins and leukocytic emigration, principally neutrophils, followed by rapid repair and healing. For convenience in this chapter, the acute inflammatory response will be divided into three sequential phases: fluidic, cellular, and reparative.

Chronic inflammation is considered to be inflammation of prolonged duration, usually weeks to months, in which active inflammation is characterized predominately by lymphocytes and macrophages, tissue necrosis, and accompanied by tissue repair, such as healing, fibrosis, and granulation tissue formation, all of which may all occur simultaneously. Chronic inflammation can be a sequela to the failure to eliminate an inciting stimulus that caused the initial acute inflammation or it can occur as a direct result of an inciting stimulus. Examples of the latter include infections by *Mycobacterium* spp.; prolonged exposure to foreign materials such as plant material

and grass awns; and autoimmune diseases, such as arthritis. Although there are some clear biologic, pathologic, and mechanistic differences and similarities between acute and chronic inflammation, discussion of acute inflammation is separated from chronic inflammation (covered in [Chapter 4](#)) as a matter of convenience.

Fig. 3-1 The major steps of the acute inflammatory process. (From Stevens A, Lowe JS, Young B: Wheater's basic histopathology: a colour atlas and text, ed 4, New York, 2002, Churchill Livingstone.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 3-1 Highlights of the Historical Contributions to the Understanding and Characterization of Inflammation

Contributor	Time	Contribution
Egyptians	3000 BC	Descriptions of inflammation
Celsus (Italy)	25 BC –50 AD	Four cardinal signs of inflammation: rubor (redness), tumor (swelling), calor (heat), dolor (pain)
John Hunter (Scotland)	1793	Inflammation is a <i>salutary</i> (favorable to health) effect, not a disease per se
Julius Cohnheim (Germany)	1839–1884	Observed inflamed vessels microscopically
Elie Metchnikoff (Russia)	1882	Observed and described phagocytosis
Rudolf Virchow (Germany)	1821–1902	Fifth cardinal sign of inflammation: functio laesa (loss of function); cellular injury
Sir Thomas Lewis (England)	1927	Determined that chemicals (histamine) induce vascular changes

### 3.2 BENEFICIAL AND HARMFUL ASPECTS OF INFLAMMATION

As a general rule, inflammatory responses are beneficial in the following:

- Diluting and/or inactivating biologic and chemical toxins
- Killing or sequestering microbes and neoplastic cells
- Providing wound healing factors to ulcerated surfaces and traumatized tissue
- Degrading foreign materials
- Restricting movement of appendages and joints to allow time for healing and repair

However, in some instances, excessive and/or prolonged inflammatory responses can be detrimental and are often more harmful than the inciting stimulus. In several disorders of human beings, such as myocardial infarction, cerebral thrombosis, and atherosclerosis, excessive and prolonged inflammatory responses can exacerbate the severity of the disease process. In veterinary medicine, exuberant or uncontrolled inflammatory responses occurring in certain diseases listed in [Table 3-2](#) can also result in increased severity of disease. Fortunately, basic research has resulted in a clearer understanding of the fundamental biologic interactions in the fluidic, cellular, and reparative phases of the acute inflammatory response and of the stimuli and mediators playing key roles in the chronic inflammatory response. As a result, antiinflammatory drugs—such as corticosteroids, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs)—have been developed and used to reduce the severity of the inflammatory response by modulating defined biologic pathways in the inflammatory cascade.

The disciplines of pharmacology, physiology, and molecular pathology are providing information that is leading to the evolution of more targeted, potent, and clinically efficacious antiinflammatory drugs. In the future, as veterinarians use new antimicrobials, chemotherapeutic agents, and therapies that regulate gene expression to treat disease, it may become important to precisely modify the inflammatory response with antiinflammatory drugs and continually monitor this therapy. For example, in *Mannheimia haemolytica* pneumonia of cattle, the use of targeted antiinflammatory drugs that modulate leukocyte infiltration and vascular leakage may reduce exudate in alveoli and alveolar walls and provide improved gaseous exchange and a reduction in the extent of pulmonary damage and fibrosis. At the same time, potent antibiotics or other drugs can be used to reduce bacterial proliferation.

### 3.3 OVERVIEW OF THE ACUTE INFLAMMATORY RESPONSE

The acute inflammatory response, as diagrammed in [Fig. 3-2](#), can be initiated by a variety of exogenous and endogenous stimuli that result in injury to vascularized tissue. The response to injury begins as active hyperemia, with an increased flow of blood to injured tissue secondary to dilation of arterioles and capillaries (redness and heat) facilitated by chemical mediators, such as prostaglandins, leukotrienes, and nitric oxide ([Table 3-3](#)). Active hyperemia is rapidly followed by changes in junctional complexes of endothelial cells induced by vasoactive amines, complement components C3a and C5a, bradykinin, leukotrienes, and platelet-activating factor (PAF), resulting in leakage of plasma and plasma proteins into the extracellular space (swelling and pain [stretching of pain receptors]) mainly from the postcapillary venules. The volume and protein concentration of leakage through gaps between the endothelial cells is related to the size of the gaps and the molecular weight of electrolytes and plasma proteins, such as albumin and fibrinogen. With more severe injury resulting in destruction of individual endothelial cells, hemorrhage occurs and plasma and plasma proteins can leak directly through a breach in the wall of the capillary or venule. Once activated, endothelial and perivascular cells such as mast cells, dendritic cells, fibroblasts, and pericytes can produce cytokines and chemokines that regulate the expression of receptors for inflammatory mediators and adhesion molecules.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 3-2 Selected Disorders That Are Induced or Exacerbated by Inflammatory Responses

### DISORDERS IN WHICH THE MECHANISM OF INJURY IS INFLAMMATION

Human beings: Alzheimer's disease, atherosclerosis, atopic dermatitis, chronic obstructive pulmonary disease, Crohn's disease, gout, graft rejection, Hashimoto's thyroiditis, multiple sclerosis, pemphigus psoriasis, rheumatoid arthritis, sarcoidosis, systemic lupus erythematosus (SLE), type I diabetes mellitus, ulcerative colitis, vasculitis (Wegner's, polyarteritis nodosa, Goodpasture's disease)

Cats: eosinophilic stomatitis, lymphoplasmacytic syndrome, pemphigus

Dogs: granulomatous meningoencephalitis, pemphigus, systemic and discoid lupus erythematosus

Common to many species: anaphylaxis, spondylitis, asthma, reperfusion injury, osteoarthritis, glomerulonephritis

### INFECTIOUS DISEASE EXACERBATED BY INFLAMMATION

Human beings: dysentery, Chagas' disease, cystic fibrosis pneumonia, filariasis, *Helicobacter* gastritis, hepatitis C, Influenza virus pneumonia, leprosy, *Neisseria/pneumococcal* meningitis, poststreptococcal glomerulonephritis, schistosomiasis, sepsis, tuberculosis

Dogs: *Helicobacter* gastritis

Cattle: *Mannheimia haemolytica* pneumonia, mastitis, *Mycobacterium bovis*, *Mycobacterium avium-intracellulare-paratuberculosis*

Pigs: circovirus

Ferrets/mink: Aleutian mink disease

Common to many species: vegetative valvular endocarditis

### CONDITIONS IN WHICH POSTINFLAMMATORY FIBROSIS OCCURS

Human beings: bleomycin pulmonary fibrosis, allograft rejection, idiopathic pulmonary fibrosis, hepatic cirrhosis (postviral, alcohol, or toxin), radiation-induced pulmonary fibrosis

Dogs: idiopathic pulmonary fibrosis (West Highland white dogs)

Cattle/sheep/horses: plant toxins (hepatic fibrosis)

Modified from Nathan C: *Nature* 420:846-851, 2002.

Fig. 3-2 The principal cellular and vascular responses during the inflammatory response. The majority of leukocyte transmigration and hemorrhage occurs in the capillaries and postcapillary venules. (Modified from McCance KL, Huether SE: Pathophysiology: the biologic basis for diseases in adults and children, ed 3, St Louis, 1998, Mosby.)

## Pathologic Basis of Veterinary Disease, 4th Edition

The plasma proteins and fluid that initially accumulate in the extracellular space in response to injury form a transudate. A transudate is a fluid that lacks protein (specific gravity <1.012 [ $<3$  g of protein/dL]) and cellular elements (<1500 leukocytes/ $\mu$ L), and is essentially a balanced electrolyte solution—an ultrafiltrate of plasma. Most commonly the formation of a transudate is due to hypertension in veins and capillaries or hypoproteinemia resulting in edema; however, transudates occur in the early stages of the acute inflammatory response when intercellular gaps that open between endothelial cells are so small that only water and electrolytes can pass through them. In time, neutrophils and additional protein can enter injured areas resulting in the formation of an exudate. An exudate is an opaque and often viscous fluid (specific gravity >1.020) that contains more than 3 g of protein/dL and more than 1500 leukocytes/ $\mu$ L. As will be discussed in a later section, the morphologic classification of inflammatory responses into categories such as serous, fibrinous, and/or suppurative is based on the character of the fluid that leaks and of the leukocytes that migrate from vessels into the extracellular space.

Fibrinogen is an important plasma protein in exudates that polymerizes in extravascular tissues to form fibrin. Plasma dilutes the effects of the inciting stimulus, whereas polymerized fibrin confines the stimulus to an isolated area, thus preventing its movement into adjacent tissue. This confinement provides leukocytes with a well-defined target for migration during the cellular phase of the acute inflammatory response. Neutrophils are the first leukocytes to enter the exudate, and their accumulation in the exudate after they liquify is termed “pus.” Neutrophils have a variety of cytoplasmic granules, such as lysosomes, containing antimicrobial peptides and proteins as well as matrix metalloproteinases, elastases, and myeloperoxidases that kill pathogens and degrade foreign material by two mechanisms: (1) phagocytosis and fusion with primary and secondary lysosomes and (2) secretion of the contents of granules into the exudate. This latter mechanism can often result in severe tissue injury. Fibrin and its products have additional activities, including chemotactic properties and blood clotting. It is also forms a framework during the initial stages of wound healing (see [Chapter 4](#)).

Neutrophils and other leukocytes do not migrate randomly to find areas of tissue injury. Fortunately, microbes, foreign materials, and some neoplastic cells release chemoattractant molecules into the exudate that diffuse through the exudate to encounter capillaries and venules. As would be expected, the greatest concentration of chemoattractant would exist nearest the microbes or foreign material, with the concentration decreasing in a gradient-like manner at distances away from the source. This process forms a “chemotactic gradient” that essentially creates a pathway for leukocytes to follow to reach the site of tissue injury. Chemoattractants activate receptors and molecules on neutrophils that result in neutrophil (1) movement and attachment to the luminal surface of capillaries and venules, (2) migration through the intercellular junctions formed by gaps between endothelial cells, and (3) migration within the exudate up the concentration gradient to the source of injury. This transmigration process is called the leukocyte adhesion cascade. This cascade has a well-characterized sequence of events occurring on the luminal surface of endothelial cells. These events, discussed in detail in a later section, include capture, rolling, slow rolling, firm adhesion, and transmigration of leukocytes into the exudate.

The reparative phase of the acute inflammatory response begins early and is only completed after the stimulus-causing injury is removed. This matter is not of minor consequence because failure to remove the stimulus can result in exuberant proliferation of granulation tissue in response to chronic unresolved injury. In the reparative phase, necrotic cells and tissue are replaced by differentiation and regeneration of epithelial and mesenchymal stem cells, by filling the defect with connective tissue and covering the denuded surface by

## Pathologic Basis of Veterinary Disease, 4th Edition

---

reepithelialization (see [Chapter 4](#)). When the acute inflammatory response is completed in the proper sequence and the stimulus of injury is removed, the injured tissue returns to normal structure and function, and the inflammatory process is terminated.

### 3.4 STIMULI INDUCING THE ACUTE INFLAMMATORY RESPONSE

There are two classes of stimuli, endogenous and exogenous, capable of causing injury to cells and tissue and inducing the acute inflammatory response. Endogenous stimuli include those that primarily cause autoreactive inflammatory responses, such as newly developed antigens from degenerate, dysplastic, or neoplastic cells and hypersensitivity reactions. Exogenous stimuli include microbes such as viruses, bacteria, protozoa, and metazoan parasites; foreign bodies such as plant fibers and suture material; mechanical stimuli such as traumatic injury; physical stimuli such as thermal or freezing injury, ionizing radiation, and microwaves; chemical stimuli such as caustic agents, poisons, and venoms; and nutritive stimuli such as ischemia and vitamin deficiencies.

The acute inflammatory response to endogenous and exogenous stimuli occurs simultaneously with activation of the innate immune system. Innate immunity is a nonspecific defense against potentially harmful environmental stimuli and consists of the following:

- Physical barriers and microenvironments provided by the lining epithelia of the skin (low pH, lactic and fatty acids) and mucosal surfaces such as the respiratory and reproductive tracts (mucociliary activity) and alimentary system (saliva, mucous secretions, and peristalsis)
- Molecular products released by mucosal epithelia, such as lactoferrin, antimicrobial peptides (alpha [ $\alpha$ ] and beta [ $\beta$ ] defensins, anionic peptide), and surfactant proteins
- Preformed (in cytoplasmic granules) and synthesized (released from cell immediately after synthesis) chemical mediators from effector cells distributed in the connective tissue of these barriers, such as mast cells (histamine and tumor necrosis factor [TNF]- $\alpha$ ), leukocytes (cytokines, degradative enzymes), and macrophages (cytokines)
- Effector molecules in the blood, such as plasma proteases (complement, kinin, and clotting systems) and in certain nerve fibers (sensory fibers, C-reactive fibers) that release substance P

The physical and biologic stimuli that activate the acute inflammatory and innate immune responses can exert their actions directly on effector cells in mucosal surfaces and vascularized connective tissue, on effector molecules in the blood, on endothelial cells, or on a combination of these components. The location, severity, and clinical signs of the acute inflammatory response depend on the route of exposure, such as dermal, alimentary, respiratory, urinary, or hematogenous, and the physical or biologic characteristics of the stimulus. More specifically, stimuli of the acute inflammatory response include but are not limited to visible and ultraviolet light spectra (sunburn and photosensitization),  $\gamma$ -radiation, blunt force trauma (abrasion, bruising, incision, and laceration), thermal injury (hot and cold), chemotherapeutics, environmental chemicals, microbial molecules (lipids and proteins), venom (insect, snake, and reptile), and responses of the adaptive immune system (type I to IV hypersensitivities) to microbial and environmental antigens. Stimuli must either penetrate (light spectra) or break/penetrate (microbes and foreign bodies) epithelial barriers of the skin and alimentary, urinary, and respiratory systems to irritate the tissue and incite an acute inflammatory response. When microbes cross these barriers, they immediately encounter tissue macrophages and other leukocytes that express membrane pattern-recognition receptors (Toll-like receptors [TLRs]). There are currently 23 known TLRs that recognize a few highly conserved ligands in microbes called pathogen-associated molecular patterns. Of the 23 TLRs, binding ligands have been characterized for only TLRs 1 through 11 to date. These patterns include the expression of

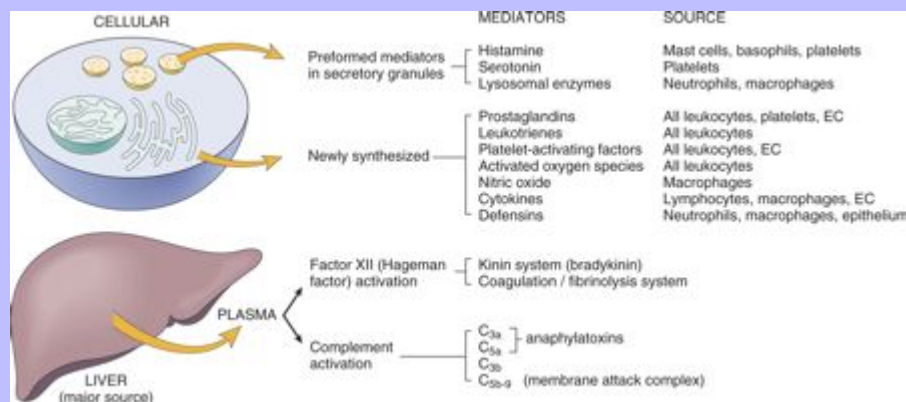

106

107

## Pathologic Basis of Veterinary Disease, 4th Edition

lipopolysaccharide (LPS) (gram-negative bacterial cell wall), lipoteichoic acids (gram-positive bacterial cell wall), mannose, peptidoglycan, bacterial DNA, N-formylmethionine (in bacterial proteins), double-stranded RNA (viruses), and glucans (fungal cell walls). When these molecular patterns are recognized by receptors, such as TLRs, on macrophages, leukocytes, and mucosal epithelia, they trigger the release of chemokines and cytokines, and cellular activation, all of which initiate and/or participate in the acute inflammatory response.

**Fig. 3-3 Chemical mediators of inflammation.** EC, Endothelial cells. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

In contrast to the innate immune system, adaptive immunity results in an antigen-specific immune response, the production of protective antibodies, and effector leukocytes that attempt to eliminate the inciting stimulus of injury, and the generation of memory cells that make subsequent adaptive immune responses against a specific microbial antigen more efficient. Because acute inflammation is a vasocentric provoked response, it would be reasonable to assume that just about any exogenous or endogenous stimulus could induce inflammation. In reality, this assumption is true, but because the inflammatory response has numerous redundant checks and balances that regulate the occurrence and severity of expression of the response, harmful effects of inflammation are minimized.

The effects of inflammatory stimuli are manifested through a group of biologic molecules called the chemical mediators of inflammation, which include vasoactive amines, such as histamine and serotonin; plasma proteases, such as complement, kinin, and clotting system proteins; lipid mediators, such as arachidonic acid metabolites; PAF; cytokines; chemokines; and nitric oxide (Fig. 3-3). Mast cells are rich in histamine and many of the chemical mediators listed previously. Mast cells are widely distributed in connective tissue adjacent to blood vessels, and alterations in the permeability of these vessels in the fluidic phase of the acute inflammatory response often occur as the result of mast cell activation. Histamine, preformed in mast cell granules, is released through a process called degranulation. Bradykinin, another vasoactive amine, is produced during vascular and/or endothelial cell injury. Both histamine and bradykinin cause changes in the caliber of arterioles, capillaries, and postcapillary venules and permeability changes in capillaries and postcapillary venules. These changes occur early in the fluidic phase of the acute inflammatory response and are quickly followed by the cellular phase.

### 3.5 FLUIDIC (EXUDATIVE) PHASE OF THE ACUTE INFLAMMATORY RESPONSE

In general, normal vascular capillaries limit the exchange of molecules to those less than 69,000 MW, the size of albumin. The exchange of small molecules and water between the vessel lumen and the interstitial space is

107

## Pathologic Basis of Veterinary Disease, 4th Edition

extremely rapid. For example, the water of plasma is exchanged with the water of the interstitial space 80 times before the plasma can move the entire length of the capillary. Physiologically, increased amounts of fluid can pass across the vascular wall when there is: (1) excessive hydrostatic pressure caused by hypertension and/or sodium retention, (2) decreased plasma proteins (colloid), or (3) lymphatic and/or venous obstruction. If fluid leakage is excessive, edema (transudate) develops. If the leakage is not excessive and postcapillary venules and lymphatic vessels are functioning normally, all of the fluid released from arterioles and small capillaries is returned to the circulation via paracellular gaps of postcapillary venular and lymphatic vessels. During acute inflammatory responses, there is a net outflow of fluid from arterioles, capillaries, and venules into extracellular tissue (Fig. 3-4).

108

The principal function of the fluidic phase of the acute inflammatory response is to dilute and localize the stimulus. The sequence of vascular events in the acute inflammatory response includes the following:

- Increased blood flow to the site of injury
- Increased permeability of capillaries and postcapillary venules to plasma proteins and leukocytes (chemical mediators of inflammation)
- Emigration of leukocytes (inflammatory mediators and the leukocyte adhesion cascade) into the exudate

In this phase there is an immediate vasocentric reaction (arterioles, capillaries, and postcapillary venules) to the stimulus.

Initially, arterioles dilate and capillary beds in the affected area expand in volume to accommodate an increased blood flow (heat and redness) in response to the stimulus (Fig. 3-5). Secondly, vascular flow through the capillary beds is then slowed as a result of permeability changes induced by chemical mediators. Reduced vascular flow results from plasma that becomes more viscous following leakage of water from capillary beds into extracellular space. Microscopically, capillaries are often packed with erythrocytes as a result of hemoconcentration and viscosity changes caused by leakage of fluid from the capillaries and postcapillary venules into the extravascular space. This process results in stasis of blood flow and provides a microenvironment that facilitates leukocytic margination along the luminal surface of endothelial cells before their emigration through intercellular junctions of endothelial cells into the inflammatory exudate in the extravascular space. Changes in capillary flow and permeability serve to dilute, isolate, and confine the stimulus within extravasated transudates and exudates.

### 3.5.1 ENDOTHELIAL CELL DYNAMICS DURING THE ACUTE INFLAMMATORY RESPONSE

Endothelial cells are the interface between plasma in the lumen and the perivascular connective tissue. Endothelial cells are polarized cells (luminal versus abluminal surfaces) that are adapted to fit the physiologic needs of the vascular bed of the organ in which they reside. Transport across the endothelial cell layer occurs by: (1) transcytosis (transcellular passage) via small vesicles and caveolae or (2) paracellular passage.

Transcytosis, the process of transporting substances across the endothelium by uptake into and release from coated vesicles, facilitates the transport of albumin, low-density lipoproteins (LDLs), metalloproteinases, and insulin. Paracellular passage allows transport of water and ions between cells (cell junctions). Paracellular passage is especially active in postcapillary venules. Roughly 30% of endothelial cell junctions in postcapillary venules can open to a width of 6  $\mu\text{m}$ , roughly the width of a red blood cell.

108

109

**Fig. 3-4 Blood pressure and plasma colloid osmotic forces in normal and inflamed microcirculation. A, Normal hydrostatic pressure (red arrows) is about 32 mm Hg at the arterial end of a capillary bed and 12 mm Hg at the venous end; the mean colloid osmotic pressure of tissue is approximately 25 mm Hg (green arrows), which is equal to the mean capillary pressure. Although fluid tends to leave the precapillary arteriole, it is returned in equal amounts via the postcapillary venule, so that the net flow (black arrows) in or out is zero. B, Acute inflammation. Arteriole pressure is increased to 50 mm Hg; the mean capillary pressure is increased because of arteriolar dilation, and the venous pressure increases to approximately 30 mm Hg. At the same time, osmotic pressure is reduced (averaging 20 mm Hg) because of protein leakage across the venule. The net result is an excess of extravasated fluid. (A and B, From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)**

**Fig. 3-5 The major local manifestations of acute inflammation compared with normal.** (1) Vascular dilation (causing erythema and warmth), (2) extravasation of plasma fluid and proteins (edema), and (3) leukocyte emigration and accumulation in the site of injury. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Leakage of fluid from the vasculature can occur within seconds after a stimulus induces the acute inflammatory response. The mechanisms by which this leakage occurs depend on the biologic and physical characteristics of the inciting stimulus. Mechanisms of vascular extravasation in the acute inflammatory response are illustrated in Fig. 3-6 and can include the following:

- Opening of junctional complexes (endothelial gaps) between endothelial cells
- Direct injury that results in necrosis and detachment of endothelial cells, as occurs with certain viral and protozoal infections
- Leukocyte-dependent injury that results in necrosis and detachment of endothelial cells and is induced by enzymes and mediators released from leukocytes during the transmigration phase of the acute inflammatory response
- Increased endothelial cell transcytosis

109

110

Fig. 3-6 **Diagrammatic representation of five mechanisms of increased vascular permeability in inflammation.** VEGF, Vascular endothelial growth factor. (From Cotran RS, Kumar V, Collins T, Robbins SL: Robbins pathologic basis of disease, ed 6, Philadelphia, 1999, Saunders.)

Endothelial gaps, resulting in vascular leakage, can occur by (1) contraction (actin/myosin) of apposing endothelial cells, the most common mechanism of extravasation, and through (2) the reorganization of the cytoskeletal microtubule and microfilament proteins within the endothelial cell, resulting in the formation of gaps between endothelial cells. In either of these two types of endothelial cell gap formation, the gaps result from the opening of junctional complexes between endothelial cells. The formation of gaps due to endothelial cell contraction occurs in postcapillary venules where there is a high density of receptors for histamine, serotonin, bradykinin, and angiotensin II. Gaps formed by cytoskeletal reorganization occur most commonly in postcapillary venules and, to a lesser extent, in capillaries in response to cytokines, such as interleukin (IL)-1 and TNF and hypoxia. Gap formation is transient and lasts 15 to 30 minutes after the stimulus occurs. Vascular leakage resulting from direct injury of endothelial cells is caused by endothelial cell necrosis and detachment of the cell from the underlying basement membrane and establishes conditions favorable for the activation of the platelet, clotting, and complement cascades. This type of extravasation usually occurs immediately after necrotizing injury induced by, for example, thermal injury, chemotherapeutics, and bacterial cytotoxins, and it affects arterioles, capillaries, and postcapillary venules. Vascular leakage resulting from leukocyte-induced injury results from neutrophils and other leukocytes interacting with endothelial cells during the leukocyte adhesion cascade. Activated leukocytes release reactive oxygen species, such as singlet oxygen and oxygen free radicals, and proteolytic enzymes, such as matrix metalloproteinases and elastase from lysosomes during degranulation of the cells, which then result in endothelial cell necrosis and detachment and thus an increase in vascular permeability. This type of extravasation usually affects capillaries and postcapillary venules.

### 3.6 CELLULAR PHASE OF THE ACUTE INFLAMMATORY RESPONSE

The principal function of the cellular phase of the acute inflammatory response is to deliver leukocytes into the exudate that has sequestered the site of injury so they can internalize stimuli through phagocytosis and, as required, kill and/or digest the stimulus. Neutrophils, eosinophils, basophils, monocytes, and lymphocytes play an integral role in protecting the mucosas, skin, and other surfaces of the body, such as the pleura, pericardium, and peritoneum, from infection by microbes through phagocytosis or release of proteolytic degradative enzymes, chemical mediators, and reactive oxygen species. Neutrophils also have an important role in responding to foreign materials and toxins and in responding to neoplastic cells.

The movement of leukocytes from the lumina of capillaries and postcapillary venules into the interstitial connective tissue occurs through a process called the leukocyte adhesion cascade ([Fig. 3-7](#)). This process is actually initiated during the fluidic phase of the acute inflammatory response and is driven by chemokines, cytokines, and chemoattractant substances such as complement. Vasodilation and permeability changes result in the slowing of blood flow and lead to changes in hemodynamic forces and the movement of leukocytes to the periphery of the vascular lumen in apposition to the surface of endothelial cells. This process is called margination. When the surface of the endothelium becomes lined by leukocytes, this outcome, when observed microscopically, is called pavementing ([Fig. 3-8](#)). Finally, leukocytes migrate between endothelial cells to enter the exudate through a process called emigration or transmigration. The leukocyte adhesion cascade has a well-characterized sequence of events including: tethering (capture), rolling, slow rolling, activation and firm adhesion, and transmigration of leukocytes toward a chemotactic stimulus. Each of these steps is important in the process of eliminating the stimulus because blocking any of these steps results in fewer numbers of leukocytes in the exudate. Temporally, tethering, rolling, slow rolling, activation and firm adhesion, and transmigration all occur concurrently, involving different leukocytes in the same capillaries and postcapillary venules. This process is mediated by the interaction of ligands expressed on the surface of neutrophils, lymphocytes, and macrophages and their receptors expressed on luminal surfaces of activated endothelial cells ([Table 3-4](#)). Chemokines and cytokines influence this process by modulating the surface expression and/or avidity of these adhesion molecules. Adhesion

## Pathologic Basis of Veterinary Disease, 4th Edition

molecules are divided into: (1) selectins (E-, L-, and P-selectin), (2) integrins (very late antigen [VLA] family of  $\beta_1$  integrins;  $\beta_2$  integrins [Mac-1, LFA-1, p150,95,  $\alpha\beta_2$ ]), (3) cytoadhesion family (vitronectin,  $\beta_3$  integrins, and  $\beta_7$  integrins used predominately by lymphocytes), (4) the immunoglobulin superfamily (intercellular adhesion molecule [ICAM-1 to ICAM-3], vascular cell adhesion molecule [VCAM-1], platelet-endothelial cell adhesion molecule [PECAM-1], and mucosal addressin adhesion molecule-1 (MAdCAM-1)), and (5) other molecules such as CD44 (Table 3-5).

110

111

**Fig. 3-7 Leukocyte adhesion cascade.** The leukocyte adhesion cascade includes tethering (capture) and rolling, which are largely mediated by L- and P-selectins and their receptors. Upon activation of leukocytes and endothelial cells, there is proteolytic cleavage of L-selectin molecules and enhanced expression of  $\beta_2$  integrins (Mac-1; CD11a/CD18) by leukocytes and intercellular adhesion molecule-1 (ICAM-1) by endothelial cells. Once leukocytes are attached to the vascular endothelium, they adhere to platelet-endothelial cell adhesion (PECAM-1) molecules present at the endothelial cell junction and transmigrate through the junction into the perivascular tissue, where they express  $\beta_1$  integrins that adhere to extracellular matrix proteins such as laminin, fibronectin, vitronectin, and collagen. The process is mediated by chemokines (CXCL8; interleukin-8), complement fragments, vasoactive amines, cytokines, and membrane-derived mediators such as platelet-activating factor and leukotrienes. Inhibition of this process is increasingly becoming possible with specific “molecular” agonists that inhibit selectin, ICAM-1, and integrin binding. ## Pathologic Basis of Veterinary Disease, 4th Edition

Fig. 3-8 **Pavementing of neutrophils, acute inflammation, arteriole.** H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

Tethering (capture) (Fig. 3-7) occurs after margination and represents the first contact leukocytes have with the luminal surfaces of endothelial cells. Tethering occurs by transient, weak binding interactions between the selectin family of adhesion molecules and their receptors. During tethering, leukocytes temporarily bind to endothelia and then release, resulting in a closer association between the leukocyte and endothelial cell membranes and reduced speed of the traveling leukocyte. This process is mediated by selectins, including L-selectin expressed by neutrophils and P-selectin, a carbohydrate binding molecule stored in Weibel-Palade bodies of endothelial cells and  $\alpha$ -granules of platelets. L-selectin is expressed on all leukocytes and binds sialyl Lewis X receptor (and other receptors) on endothelial cells. P-selectin molecules expressed on endothelial cell surfaces bind to P-selectin glycoprotein ligand-1 (PSGL-1) present on neutrophils, eosinophils, monocytes, and lymphocytes. E-selectin also mediates leukocyte-endothelial cell adherence and is expressed on endothelial cell surfaces for binding glycoprotein receptors expressed on leukocytes.

111

112

Table 3-4 Endothelial Cell/Neutrophil Adhesion Molecules

Endothelial Molecule	Leukocyte Receptor	Major Role
P-selectin	Sialyl-Lewis X PSGL-1	Rolling (neutrophils, monocytes, lymphocytes)
E-selectin	Sialyl-Lewis X ESL-1, PSGL-1	Rolling, adhesion to activated endothelium (neutrophils, monocytes, T lymphocytes)
ICAM-1	CD11/CD18 (integrins) (LFA-1, Mac-1)	Adhesion, arrest, transmigration (all leukocytes)
PECAM-1	PECAM-1	Transendothelial cell migration
JAM A	JAM A, LFA-1	Transendothelial cell migration
JAM C	JAM B, Mac-1	Transendothelial cell migration

From Cotran RS, Kumar V, Collins T, Robbins SL: *Robbins pathologic basis of disease*, ed 6, Philadelphia, 1999, Saunders.  
ESL-1, E-selectin ligand-1; ICAM-1, intercellular adhesion molecule-1; JAM, junctional adhesion molecule; LFA-1, lymphocyte function antigen-1; Mac-1, macrophage antigen-1; PECAM-1, platelet endothelial cell adhesion molecule-1; PSGL-1, P-selectin glycoprotein ligand-1; VCAM-1, vascular cell adhesion molecule-1; VLA, very late antigen.

Rolling, the next step after tethering, is the process in which L-selectin and also P-selectin mediated attachments result in continued contact between the leukocyte and endothelium (Fig. 3-7). During rolling, bonds are formed at the leading edge of the rolling leukocyte and broken at the trailing edge. Leukocytes begin to roll along the surface of the endothelium under the pressure of blood flow hemodynamics. Even slight disturbances such as surgical manipulation, heat, temporary ischemia, and mast cell products induce rolling of neutrophils along the surface of vascular endothelial cells. Rolling then progresses to the slow rolling stage. Slow rolling occurs following

## Pathologic Basis of Veterinary Disease, 4th Edition

---

interaction of endothelial cells with proinflammatory cytokines, such as  $\text{TNF-}\alpha$  and the expression of E-selectin by endothelia and  $\alpha_2$  integrins (CD11a [LFA-1] and CD11b [Mac-1]) by neutrophils. By slowing leukocyte transit time through capillaries and postcapillary venules, combined with the continual close proximity of slow rolling leukocytes to the endothelium, and the expression of chemokines on the surface of endothelial cells, these events contribute to the proper microenvironment for slow rolling to occur and for progression to the “firm adhesion” stage.

Firm adhesion (Fig. 3-7) occurs after leukocytes have progressed through the rolling and slow rolling stages. For firm adhesion to occur, neutrophils and endothelial cells become activated by a variety of cytokines (such as interleukin-1 [IL-1], interleukin-6 [IL-6], tumor necrosis factor [TNF]), complement factors (C5a), platelet activating factor (PAF), platelet-derived growth factor (PDGF), chemokines, and other inflammatory mediators. Once neutrophils are activated, L-selectin molecules are proteolytically cleaved from the neutrophil surface, and the neutrophils express a new set of membrane proteins (integrins) by rapid exocytosis of cytoplasmic vesicles. Firm adhesion to endothelial cells is mediated by binding of  $\beta_2$  integrin molecules, such as Mac-1 (CD11a/CD18) expressed on neutrophils to ICAM-1 and other ICAM molecules on endothelial cells. E-selectin adherence also contributes to the process of firm adhesion. There are four  $\beta_2$  integrins (LFA-1, Mac-1, p150, 95, and  $\alpha\beta_2$ ), each of which are heterodimers that differ only in their subunit CD11 a, b, c, and d for LFA-1, Mac-1, p150,95, and  $\alpha\beta_2$ , respectively. CD18 (the  $\beta$ -subunit) is identical in all four  $\beta_2$  integrins. Three  $\beta_2$  integrins (LFA-1, Mac-1, and p150,95) are involved with leukocyte adherence; however, the  $\beta_2$  integrin  $\alpha\beta_2$ , which was first identified in dogs and subsequently in human beings, is apparently not meaningfully involved with the adherence of neutrophils or other leukocytes to endothelium.

In postcapillary venules, neutrophil movement decreases from 10  $\mu\text{m/sec}$  to a complete stop after margination.

Firmly adhered leukocytes emigrate (transmigrate) through the endothelial layer between endothelial cells if an exogenous chemoattractant is present in the exudate. A number of leukocyte adhesion molecules are involved in this process. Neutrophils and other leukocytes transmigrate between endothelial cells at the intercellular

112

114

junctions. PECAM-1, a molecule that is present on endothelial cell membranes and junctional adhesion molecules (JAMs) A, B, and C mediate adherence activities and the adherence process. Contributions to this process also include  $\beta_2$  integrin binding of ICAM-1 and E-selectin binding. Pseudopodia from neutrophils and other leukocytes extend between endothelial cells and come into contact with and bind to the basement membrane (composed of laminin and collagens) and subjacent extracellular matrix proteins (proteoglycans, fibronectin, vitronectin). This binding interaction is mediated, at least in part, by the  $\beta_1$  integrins. Transendothelial migration of neutrophils across the vascular wall leads to accumulation of neutrophils in the perivascular connective tissue stroma within the inflammatory exudate and can be accompanied by vascular leakage and injury. Neutrophils, drawn out of the blood vessels by chemoattractants, now migrate to the stimulus along the established chemotactic gradient.

### 3.6.1

#### LEUKOCYTE ADHESION DEFICIENCIES

Leukocyte adhesion deficiencies (LADs) type I, type I variant, and type II and E-selectin deficiency occur due to one or more defects in the sequence of steps leading to migration of leukocytes into the site of inflammation. These deficiencies occur in human beings and recently have been recognized and characterized in cattle and dogs (Table 3-6). The debilitation that often occurs in human beings and animals with severe forms of leukocyte adhesion deficiencies underscores the importance of leukocytes in host defense and the vital nature of the adhesion molecules integral to the transmigration process.

Cattle, dogs (Irish setters), and human beings with LAD type I lack functional expression of the  $\beta_2$  integrins. They often have high numbers of neutrophils in the blood, which can exceed 125,000/ $\mu$ L in cattle; however, these neutrophils have impaired passage across vascular walls (Fig. 3-9) and numerous other functional abnormalities related to inadequate membrane adherence activity. Cattle with bovine leukocyte adhesion deficiency (BLAD) develop severe gingivitis, tooth loss, oral ulcers, enteric ulcers, cutaneous ulcers, abscesses that lack pus formation, and pneumonia (Fig. 3-10). Most affected cattle die within few days or weeks after birth due to diarrhea and/or pneumonia. The hallmark lesion histologically is a sparse infiltration of neutrophils into ulcerated mucosal surfaces or pulmonary alveoli, despite high numbers of neutrophils within lumina of submucosal and pulmonary septal blood vessels. There are no effective treatments for calves and Irish setters with LADs, although cattle with BLAD can survive into adulthood with intensive medical care.

114

115

**Table 3-6 Molecular Defects of Various Leukocyte Adhesion Molecule Deficiencies Identified in Animals and Humans**

Name	Species	Molecular Defect	Severity
LAD, type I	Human beings	Mutations in CD18, CD11	Mild to severe
	Bovine	Mutation in CD18	Severe
	Canine	Mutation in CD18	Severe
LAD, type II	Human beings	Impaired selectin fucosylation	Severe
LAD variant	Human beings	Proteolysis of E-selectin	Severe

LAD, Leukocyte adhesion deficiency.

**Fig. 3-9 Bovine leukocyte adhesion deficiency, intravascular neutrophils partially adhered (rolling) on endothelial cells, capillary, alveolar septum, lung.** The septum is thickened because of two neutrophils (*A*) within the septal wall and a neutrophil (*B*) within the lumen of a vascular capillary (adherence). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

**Fig. 3-10 Bovine leukocyte adhesion deficiency (BLAD), gross and microscopic characteristics.** **A**, The oral cavity has irregularly arranged molar teeth (*arrow*), oral ulcers (*arrowhead*), and grass material within the oral cavity secondary to impaired mastication. **B**, The serosa of the small intestine is thickened (*arrow*), and there are fibrous tags between serosal surfaces (*arrowheads*). **C**, Microscopically the mucosa underlying the areas of thickened serosa is ulcerated and covered by cell debris. Vascular lumina contain elevated numbers of neutrophils, which do not adhere to the vascular endothelium (*arrows*) despite the ulcerated and “inflamed” mucosa. Lymphocytes, macrophages, and plasma cells are present perivascularly in Peyer's patches, but the lymphoid tissue virtually lacks neutrophils. The lack of neutrophil adherence to the vascular endothelium and of infiltration into the perivascular areas is caused by the lack of expression of  $\beta_2$  integrins in BLAD. H&E stain. (**A**, **B**, and **C**, Courtesy Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

The deficiency in  $\beta_2$ -integrin expression in Holstein calves is due to a single point mutation (adenine → guanine) at position 128 resulting in a single amino acid change (aspartic acid → glycine) in the  $\beta$ -subunit (CD18) of the

## Pathologic Basis of Veterinary Disease, 4th Edition

$\beta_2$  integrins. This defect occurs in a highly conserved extracellular region (amino acids 96 through 389) of the protein. A second, silent mutation has also been detected in cattle with BLAD and does not alter the amino acid sequence. In Irish setters with canine leukocyte adhesion deficiency (CLAD), there is a single missense mutation resulting in a G to C transversion at nucleotide 107 of the cDNA sequence, resulting in a serine that replaces a highly conserved cysteine.

A variant form of LAD type I has been described in human beings in which  $\beta_2$  integrins are expressed but do not undergo conformational change upon leukocyte stimulation. In 1992 a second form of LAD was discovered: LAD type II. In LAD type II, patients lack sialoglycoproteins that are utilized for selectin-mediated adherence. Their CD18 binding remains intact. Interestingly, these patients suffer from the same types of lesions and infections as do patients with CD18 deficiency. Therefore these observations demonstrate the importance of CD18-independent adherence. Finally, as indicated earlier, individuals with clinical disease similar to LAD type I and II (recurrent mucosal infections) had expression of adhesion molecules but enhanced proteolytic cleavage of E-selectin.

115

3.6.2

### CADHERINS

116

Cadherins are a group of functionally related glycoproteins expressed in epithelial cells of skin and mucosal epithelium that mediate calcium-dependent, cell-to-cell adhesion. There are three cadherin subtypes: epithelial (E) cadherin or uvomorulin, placental (P) cadherin, and neural (N) cadherin. E- and P-cadherin are present in intercellular junctions (adherens). Intraepithelial lymphocytes that express  $\alpha_4\beta_7$  integrin bind to E-cadherin expressed by epithelial cells. E-cadherin is present in most epithelial cells and P-cadherin is present in the placenta and in epithelium in conjunction with E-cadherin. N-cadherin is present in neural tissue, muscle, kidney, and lens of the eye. Autoantibodies to cadherins are the basis for the skin disease pemphigus vulgaris (see [Chapter 17](#)). Cadherins are vital to innate immune activity and tissue repair.

3.6.3

### THERAPEUTIC STRATEGIES: INHIBITION OF LEUKOCYTE ADHESION MOLECULES

Inhibition of leukocyte infiltration may be useful to treat diseases such as stroke, myocardial infarction, asthma, and autoimmune diseases in human beings and laminitis, reperfusion injury postcolic, gastric dilation/volvulus, mastitis, enteritis, allergic lung disease, pneumonia, and autoimmune diseases in domestic animals. For example, studies have shown that initial neutrophil infiltration into bronchi and bronchioles of cattle with *Mannheimia haemolytica* pneumonia require functional  $\beta_2$  integrins; however,  $\beta_2$  integrins are not vital for neutrophil infiltration into alveoli. In addition, infiltration into alveoli can be inhibited by the selectin inhibitor TBC1269 (Bimosiamose, Encysive Pharmaceuticals, Bellaire, Tex). Inhibition of leukocyte infiltration during infectious diseases such as *Mannheimia haemolytica* pneumonia may prevent excessive leukocyte infiltration and leukocyte-mediated damage if combined with appropriate antibiotic therapy. Also manipulation of leukocyte infiltration into precise regions of the lung or other tissue may make it possible to “site-direct” infiltration into a location of interest. For example, it may be possible to develop inhibitors that allow leukocyte infiltration into bronchi of animals with a bronchus-specific pathogen, such as *Bordetella bronchiseptica* in dogs and pigs, but prevent infiltration into alveoli (the site of gaseous exchange). Inhibitors may also allow infiltration into the renal pelvis and cortical tubular area during ascending bacterial infections (pyelonephritis), but not glomeruli, for example.

Nonspecific types of inhibition of leukocyte adhesion molecules include NSAIDs, corticosteroids, and drugs that inhibit the production or release of inflammatory cytokines. Specific inhibitors to adhesion molecules include selectin antagonists (TBC1269 [Encysive Pharmaceuticals], Efomycine [Bayer Pharmaceutical Group,

## Pathologic Basis of Veterinary Disease, 4th Edition

Leverkusen, Germany], Cylexin [Epimmune Inc., San Diego, Calif]),  $\beta_1$  integrin antagonists (TBC4746 [Encysive Pharmaceuticals], BIO1211 [Biogen Inc., Cambridge, Mass]), and antagonists to  $\beta_2$  integrins (A304470 [Abbott Laboratories, Abbott Park, Ill] and BIRT377 [Boehringer Ingelheim Pharmaceuticals, Ingelheim, Germany]). Other inhibitors include peptides derived from fibronectin fragments, monoclonal antibodies, and small inhibitory RNA (siRNA). These drugs are being tested in animal models of myocardial infarction, stroke, multiple sclerosis, graft-versus-host disease, psoriasis, rheumatoid arthritis, inflammatory bowel disease, asthma, and colitis. Some of these drugs are available commercially or are being used in human clinical trials.

### 3.7 REPARATIVE PHASE OF THE ACUTE INFLAMMATORY RESPONSE

#### 3.7.1 OUTCOMES OF THE ACUTE INFLAMMATORY RESPONSE

There are four main outcomes of acute inflammation:

- Resolution (the return to normal structure and function)
- Healing by fibrosis
- Abscess formation
- Progression to chronic inflammation

These outcomes are determined by the severity of tissue damage, the ability of cells to regenerate, and the biologic characteristics of the stimulus that caused the injury. In the acute inflammatory response, the desired outcome is resolution; that is, the complete return of normal structure and function. Resolution occurs if:

- The acute inflammatory response is completed in the correct sequence
- Macrophages and lymphatic vessels remove the exudate
- The inciting stimulus is eliminated
- The stroma (connective tissue) of the affected tissue is intact and can provide support for regeneration of epithelial cells
- Denuded or necrotic epithelial cells are replaced by regeneration of adjacent epithelial cells on an intact basement membrane

Mechanistically, the critical first stage of resolution involves the killing and/or removal of the inciting stimulus, neutralization or decay of chemical mediators, return to normal of vascular flow and capillary permeability, cessation of leukocyte emigration, apoptotic cell death of remaining neutrophils in the exudate, and the removal of the exudate via phagocytosis by cells of the monocyte-macrophage system and drainage to regional lymph nodes (Fig. 3-11). Regeneration is the second stage of resolution and is dependent on the availability of progenitor epithelial cells to replace lost cells and the presence of a supportive stroma and intact basement membrane for cellular migration. As an example, acute renal tubular necrosis can be caused by aminoglycoside antibiotics and results in detachment and necrosis of tubular epithelial cells from the tubular basement membrane. If the supporting stroma and basement membrane remain intact, progenitor epithelial cells can divide and migrate to replace lost cells and thus return the tubule to normal function. If the basement membrane

116

117

## Pathologic Basis of Veterinary Disease, 4th Edition

is not intact to guide the proliferating cells, functional tubules will not form. Instead, regenerative tubular epithelial cells will atrophy or form into small aggregates with syncytial giant cells. Simultaneously, the microvascular supply to the region must be restored and this occurs mechanistically by the proliferation of endothelial cells in response to molecules, such as vascular endothelial growth factor (VEGF), as discussed with wound healing in [Chapter 4](#).

**Fig. 3-11 Events in the resolution of inflammation.** (1) Return to normal vascular permeability; (2) drainage of edema fluid and proteins into lymphatics or (3) by pinocytosis into macrophages; (4) phagocytosis of apoptotic neutrophils and (5) phagocytosis of necrotic debris; and (6) disposal of macrophages. Macrophages also produce growth factors that initiate the subsequent process of repair. Note the central role of macrophages in resolution. (*Modified from Haslett C, Henson PM: Resolution of inflammation. In Clark R, Henson PM, editors: The molecular and cellular biology of wound repair, New York, 1996, Plenum Press.*)

### 3.8 EFFECTOR CELLS OF THE ACUTE INFLAMMATORY RESPONSE

#### 3.8.1 VASCULAR ENDOTHELIAL CELLS

Central to the integrity of the vasculature and any type of acute inflammatory response is the endothelial cell. Once considered simply a cell that, in the most simplistic view, offered physical separation between the blood and the surrounding tissue, endothelial cells are now known to have an extremely sophisticated role in regulating: (1) hemostasis/coagulation, (2) vascular pressure, (3) angiogenesis during wound healing, (4) carcinogenesis, (5) leukocyte homing, and (6) inflammation. During inflammation, endothelial cells have a major role through contraction, release of chemical mediators, and expression of adhesion molecules and

## Pathologic Basis of Veterinary Disease, 4th Edition

receptors that include E-selectin, P-selectin, L-selectin ligand, PECAM-1, JAM A, B, and C, and the immunoglobulin superfamily, such as ICAM-1, which serves as ligands for leukocyte  $\beta_2$  integrins.

3.8.2

### MAST CELLS AND BASOPHILS

The origin and relationship between mast cells and basophils has been a traditional point of debate and confusion. Current research clearly indicates that mast cells and basophils represent distinct cell types even though they share several morphologic and functional characteristics. Mast cells and basophils originate and differentiate in bone marrow from a common CD34<sup>+</sup> precursor cell along with other granulocytes and monocytes. Differentiation of CD34<sup>+</sup> precursor cells into mast cells or basophils is dependent on stem cell factor, a glycoprotein that acts with other cytokines and is produced in the bone marrow by fibroblasts and vascular endothelial cells. There is no evidence to suggest that basophils differentiate into tissue mast cells.

Mammalian mast cells are normally distributed throughout connective tissue adjacent to small blood and lymphatic vessels of skin and mucous membranes, which allows them to interact with resident dendritic cells (macrophages) and respond to foreign proteins and microbes in the perivascular spaces. Experimental studies suggest that cutaneous mast cells in tissue have a life span of 4 to 12 weeks depending on their location. Mast cells represent an extremely heterogeneous population of cells. In the 1960s Enerback identified two separate types of mast cells: "mucosal" and "connective tissue." The mucosal mast cells, typically located in the

117

respiratory and intestinal mucosa, can increase in numbers during some types of T<sub>H</sub>2 cell-dependent immune responses. In contrast, the connective tissue mast cells show little or no T-cell dependence. Mast cells express high affinity receptors for immunoglobulin E (IgE) (Fc  $\epsilon$ -RI) on their surface and the release of mast cell granules is stimulated by cross-linking of IgE receptors by antigens such as pollens, allergens, and parasites. Substance P released from sensory (C-reactive) nerve fibers and macrophages also causes degranulation of mast cells. Degranulation results in the release of preformed TNF- $\alpha$  histamine, neutral proteases, proteoglycans (chondroitin sulfates and heparin), serotonin (in rodent species but not human beings), tryptase, chymase, and stem cell factor into tissue. Histamine and substance P activity appears interrelated because histamine released by mast cells can downregulate release of substance P by nerve fibers, thereby reducing excessive amounts of the two proinflammatory molecules. The mast cell-substance P fiber interrelationship is an often cited example of the neuroinflammatory-neuroimmune pathways.

118

Mast cells also synthesize leukotriene C<sub>4</sub> (LTC<sub>4</sub>), PAF, prostaglandin D<sub>2</sub>, numerous cytokines, and C-C chemokines (macrophage inflammatory protein [MIP]-1- $\alpha$  and macrophage chemotactic protein [MCP]-1). The release of these mediators contributes significantly to the initiation of the acute inflammatory response. In addition, at physiologic concentrations these products likely counteract the effects of dense populations of mast cells in tissue and thus assist in regulating vascular permeability. Mast cells also release proteolytic enzymes, such as tryptase and chymase, which are involved with remodeling of the extracellular matrix. Tryptase is mitogenic to epithelial cells and likely contributes to proliferation of epithelial cells during wound repair.

Basophils are similar to neutrophils and eosinophils in that they mature in the bone marrow, circulate in the peripheral blood, are recruited into the tissue, and have a life span of several days in tissue. Basophils express high affinity IgE receptors similar to mast cells and release granules and inflammatory mediators. Basophils appear to lack heparin, have a more limited cytokine repertoire than mast cells, and release mainly IL-4 and IL-13. Basophils express CD40L and CCR3 (eotaxin receptor), both of which point to a role as a cell that can enter sites of inflammation and release regulatory cytokines where they upregulate VCAM-1 expression by endothelial cells and switch B lymphocytes to produce IgE, further contributing to the IgE type of response. Basophils can be prominent in IgE-mediated leukocyte infiltration into the mucosa of the nose, sinuses, respiratory tract, and skin, and all of these sites are particularly predisposed to allergic conditions.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The role of mast cells and basophils in IgE-mediated hypersensitivity reactions has been known for decades. These cells appear to represent critical effector cells in disorders of IgE-dependent immediate type I hypersensitivities (see [Chapter 5](#)). The release of their granules and mediators at inflammatory concentrations results in mucus secretion, accumulation of seroproteinaceous fluid in airways, bronchoconstriction, and vasodilation. The excessive release of tryptase and chymase by mast cells may enhance degradation of the extracellular matrix and contribute to fibrosis and tissue remodeling. Chemokines and cytokines from mast cells and basophils contribute to innate immune defenses and enhanced adhesion molecule expression with subsequent leukocyte infiltration.

3.8.3

### NEUTROPHILS

Neutrophils are often the first type of leukocyte recruited into the inflammatory exudate. Their purpose is to: (1) kill microbes, such as bacteria, fungi, protozoa, and viruses; (2) kill tumor cells; or (3) to eliminate foreign materials. The biologic activities of neutrophils are primarily designed to kill microbes, but if killing does not occur they can limit the growth of microbes, allowing time for adaptive immunologic responses to develop.

Neutrophils perform two important functions to accomplish their effects: (1) phagocytosis of microbes or foreign material and then fusion of the phagosome with the neutrophil's lysosomes to form a phagolysosome in which the microbes or foreign material are killed or degraded, respectively, and (2) secretion and/or release of the contents of their granules into the inflammatory exudate to enhance the acute inflammatory response. They also infiltrate areas of acute tissue necrosis, such as those that occur with ischemia in infarcts and in necrotic areas of tumors.

Neutrophils are produced in the bone marrow, circulate in the blood stream, and if not recruited into tissue by an acute inflammatory response, can enter tissue where they eventually are destroyed by macrophages via apoptosis and phagocytosis or are lost from the body by migration across mucosal surfaces, such as the alimentary and respiratory tracts. The average transit time in the blood is 10 hours, and the half-life varies between species but ranges from 5 to 10 hours; neutrophils within tissue survive from 1 to 4 days. Cytokines, such as IL-1 and TNF, and growth factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and IL-3 can increase release of neutrophils from the bone marrow and induce granulopoiesis in 2 to 4 days. GM-CSF and G-CSF are also present in tissue during acute inflammatory response and prevent apoptosis of tissue neutrophils. Growth factor withdrawal, which occurs during resolution of acute inflammation, induces apoptosis and this outcome can be accelerated by TNF. During apoptosis, neutrophils lose the capacity to degranulate and become activated, which prevents excessive tissue damage from their lysosomal enzymes and allows for their phagocytosis by macrophages.

118

119

**Fig. 3-12 Phases of phagocytosis.** **A**, Opsonized microbes (1) bind to the surface of a phagocyte and (2) are ingested into a phagocytic vacuole or phagosome (3). Lysosomes fuse with the phagosome (4), releasing their digestive enzymes into the vacuole. This process results in the formation of a phagolysosome (5), within which the microbe is killed and digested. **B**, Enlargement showing microbe opsonization. *IgG*, Immunoglobulin G; *C3b*, complement component. (*A and B*, From McCance K, Huether S: Understanding pathophysiology, St Louis, 1996, Mosby.)

Neutrophils entering tissue become activated (phagocytosis, killing, and locomotion) through stimulation by inflammatory mediators and adherence to ligands by surface adhesion molecules (Fig. 3-12). Inflammatory mediators bind receptors on neutrophils, such as: (1) G protein-linked seven membrane domain receptors for PAF, C5a, IL-8 and substance P (the neurokinin-1 receptor) and (2) single-transmembrane-domain receptors for growth factors such as GM-CSF and cytokines such as TNF. Many of these mediators induce chemotaxis; when leukocyte adhesion molecules—such as the selectins and integrins—bind their respective ligands, they induce

## Pathologic Basis of Veterinary Disease, 4th Edition

---

mitogen-activated protein kinase (MAPK) and G proteins (p-A) resulting in locomotion of neutrophils usually toward a chemotactic gradient and activation.

Neutrophils can internalize by phagocytosis large particles up to 0.5  $\mu\text{m}$  in diameter, such as microbes, foreign bodies, senescent cells, and debris. Neutrophils can internalize nonopsonized particles; however, opsonization greatly facilitates phagocytosis. The principal opsonin receptors are Fc receptors (Fc  $\gamma$ -receptor I, IIA, IIIB), which bind the Fc portion of immunoglobulins. Such binding initiates activity of the GTPase Rac-1 and the  $\beta_2$  integrin Mac-1 (CD11b/CD18), which also binds complement fragment C3bi and initiates GTPase-p. Such binding-inducing proteins and lipid kinases (e.g., protein kinase C and phosphatidylinositol 3-kinase) mediate actin assembly for formation of filopodia or lamellipodia, which surround and then internalize particles via phagocytosis by activated neutrophils. The activation process also leads to the release of calcium stored in the endoplasmic reticulum, which can induce a respiratory (oxidative) burst. Oxidative burst is the process by which nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in phagosomes catalyzes the formation of free radicals that are used to kill microbes or degrade internalized material.

Once a particle is internalized, phagosomes can “mature” by fusing with lysosomes and endosomes or remove parts of internalized particles. The fusion process is likely mediated by calmodulin, a calcium-binding protein, and soluble NSF (*N*-ethylmaleimide-sensitive factor) attachment protein receptors (SNARE; a fusion protein) that bind ligands on another vesicle to bring the membranes together for fusion. The maturation process results in lowering of the pH within the phagosome and the activation of microbicidal enzymes; NADPH oxidase, which forms oxidative radicals; and myeloperoxidase complexes. Smaller particles are taken up by receptor-mediator or nonspecific endocytosis, a process that is similar to phagocytosis.

The ability of neutrophils to kill microbes or to degrade foreign material depends largely on the contents of the neutrophil granules, which store degradative enzymes, peroxidative enzymes, adhesion molecules, and antimicrobial peptides and/or proteins. Myeloperoxidase is an enzyme used to convert hydrogen peroxide to hypochlorous acid. Hypochlorous acid, hydrogen peroxide, and a halide cofactor form the myeloperoxidase system, which is an effective microbicidal mechanism used by neutrophils to kill internalized microbes and degrade internalized substances. Defensins, cathelicidins, and antimicrobial proteins contribute to the degradation of microbes through the formation of pores in microbial membranes. They also have an effect on chemotaxis and activation of the adaptive immune response. Lactoferrin inhibits the growth of phagocytosed bacteria by sequestering free iron, and elastase hydrolyzes bacterial cell wall proteins and tissue elastin. The enzymatic contents of granules—such as gelatinase (matrix metalloproteinase 9 [MMP 9]) and myeloperoxidase—and nonenzymatic substances—such as antimicrobial peptides and lactoferrin—are also commonly released by the cell into the extracellular space and play a role in the extracellular killing of microbial pathogens and degradation of the extracellular matrix. The effects of neutrophil proteases, if not inactivated, can cause serious injury to tissue; therefore protease inhibitors are present in plasma and are present in inflammatory lesions following vascular leakage.

119

120

Neutrophil granule formation begins during myeloid cell differentiation in the bone marrow (Box 3-1). Granules are observed initially in myeloblasts and promyelocytes when immature transport vesicles bud from Golgi and fuse to form primary granules. Primary granules are also called azurophilic granules because of their affinity for the dye azure A. These granules contain myeloperoxidase, elastase, defensins, and small amounts of lysozyme. Myelocytes and metamyelocytes form secondary (specific) granules that contain defensins, lactoferrin, lysozyme, and lesser amounts of myeloperoxidase, CD11b/CD18, and elastase. Band cells, the penultimate stage of neutrophil development, form tertiary (gelatinase) granules that contain lysozyme, gelatinase (MMP 9), cysteine-rich secretory protein-3 (CRISP-3), and adhesion molecules CD11b/CD18 (Mac-1), but have smaller amounts of myeloperoxidase, lactoferrin, proteinase 3, elastase, and defensins. Band and mature neutrophils also have secretory vesicles that contain plasma proteins, alkaline phosphatase, and

## Pathologic Basis of Veterinary Disease, 4th Edition

numerous CD antigens, including CD11b/CD18 adhesion molecules. The secretory vesicles are mobilized quickly after neutrophil activation, allowing leukocyte infiltration.

Neutrophil granules have evolved phylogenetically and are specially adapted for each species. In most mammals, enzymes released into an exudate from neutrophil granules cause liquefaction of the exudate and the process results in the formation and accumulation of pus. Reptiles and birds that either lack or have reduced concentrations of these enzymes cannot liquefy the exudate, and a caseous material forms to be degraded by the

## Pathologic Basis of Veterinary Disease, 4th Edition

next available line of inflammatory cells, macrophages. Granules in chicken heterophils (the avian, rabbit, and guinea pig neutrophil equivalent is termed heterophils) have little myeloperoxidase, but concentrations are also reduced in neutrophils of cattle and pigs. Cattle and sheep neutrophils have limited lysozyme levels.

$\alpha$ -Defensins are present in rabbits, guinea pigs, hamsters, rats, and cattle neutrophils, but have not been identified in those of dogs, cats, mice, pigs, and horses. The effect of these granule differences in various animal species on host defense and neutrophil function is not fully understood.

3.8.4

### EOSINOPHILS

Eosinophils are recruited from the blood stream into vascularized connective tissue of most organs in response to eosinophil chemoattractants present in allergic and parasitic diseases. As examples, the skin, the respiratory and alimentary systems, and the liver are common organ systems in which eosinophils are present in certain inflammatory responses. Eosinophils have prominent granules that release basic proteins and when activated produce cytokines, chemokines, proteases, and oxidative radicals. This array of mediators is often released in response to helminthic infections, and eosinophilic infiltration has been more recently implicated in resistance to the development of some cancers. On the other hand, eosinophil products contribute to tissue damage in several organs, including the lungs (asthma), heart, skin, and gastrointestinal tract.

Eosinophils were first recognized as blood cells (leukocytes) having numerous cytoplasmic granules with affinity for acidic dyes such as eosin. Therefore, the name “eosinophil” (“eosin-loving”) was proposed by Ehrlich in the late 1800s for these unique cells. By 1939, eosinophils were postulated to have a role in the immune response to helminths, and by the 1970s eosinophils were well known to increase in the blood (eosinophilia) in parasitic and allergic diseases. Eosinophils are slightly larger than neutrophils. The nucleus is lobulated (bilobed) and composed primarily of heterochromatin (condensed). Eosinophil granules are known for their large size, especially in horses; are rich in arginine; and have reddish brown tinctorial properties.

120

121

Table 3-7 Morphologic Features and Function of Eosinophilic Granules

Granule Type	Morphology	Content	Function
Small granules	Few, small, homogeneous	Acid phosphatase,	Inactivate leukotrienes
Primary granules	Few, round, electron-dense	arylsulfatase	
Secondary granules (specific granules)	Electron-dense, crystalline core	Major basic protein	Toxic to parasites, tumor cells, host tissue; causes histamine release; inhibits heparin activity
	Electron-lucent matrix	Eosinophil cationic protein	Toxic to parasites, causes histamine release, antiparasitic
		Eosinophil-derived neurotoxin	Neurotoxic with H <sub>2</sub> O <sub>2</sub> /halide, microbicidal
		Eosinophil peroxidase	Microbicidal
		Catalase	Inactivates leukotrienes

Eosinophils have several types of granules listed in Table 3-7, including large specific granules, small granules, primary granules, and secondary granules. Large specific granules contain four distinct basic proteins: (1) major basic protein, (2) eosinophil cationic protein, (3) eosinophil-derived neurotoxin, and (4) eosinophil peroxidase. These proteins exert biologic effects on microbes and on the tissue in which the microbes replicate by damaging lipid membranes. In addition, histaminase and a variety of hydrolytic lysosomal enzymes, such as collagenase and gelatinase, are also present in the large specific granules. Small granules contain enzymes, such as arylsulphatases, acid phosphatases, metalloproteinases, and gelatinases. Eosinophils also elaborate cytokines, such as ILs 1, 2, 3, 4, 5, 6, 8, 10, 12, 16, GM-CSF, transforming growth factor (TGF)- $\alpha$  and TGF- $\beta$  and

## Pathologic Basis of Veterinary Disease, 4th Edition

chemokines. The contents of eosinophil granules are released in response to inflammatory stimuli in a manner similar to those used to activate neutrophils. However, products of eosinophil granules can result in extensive tissue degradation, including the degradation of collagen, which is commonly seen in eosinophilic granulomas of cats, horses, and dogs. Nearly all mast cell tumors in dogs and some mast cell tumors in cats contain eosinophils.

Major chemoattractants for eosinophils include histamine and eosinophilic chemotactic factor A (from mast cells), neutrophil peptides, C5a, cytokines (IL-4, IL-5, and IL-13) and chemokines (CCL-5, known as RANTES [regulated on activation, normal T lymphocytes expressed and secreted], and CCL-11, known as eotaxin) released from epithelial cells, eosinophils, mast cells, and helminths. 5-Oxo-6,8,11,14-eicosatetraenoic acid (5-oxo-ETE) is a strong activator of human eosinophils with a chemotactic potency comparable with those of eotaxin and RANTES, both of which enhance 5-Oxo-ETE-induced chemotaxis. 5-Oxo-ETE and these chemokines contribute to the accumulation of eosinophils in the respiratory system in diseases such as asthma.

3.8.5

### MONOCYTES AND MACROPHAGES

Monocytes and macrophages are components of the monocyte-macrophage system. The number of macrophages in tissue is maintained by: (1) influx of monocytes from the blood, (2) proliferation of recruited monocytes locally in tissue, and (3) biologic turnover of macrophages via apoptotic cell death (life span in tissue of less than 3 weeks). During inflammatory responses, monocytes that have receptors (IgG Fc-domains, C3b) for chemical mediators of inflammation exert migratory, chemotactic, pinocytic, and phagocytic activities in response to inflammatory stimuli. When monocytes emigrate into tissue, they undergo additional differentiation to become tissue macrophages. There are two types of tissue macrophages: macrophages that reside within specific organs/tissue (free macrophages and fixed macrophages) and macrophages derived from monocytes in response to inflammatory stimuli. Macrophages residing in organs/connective tissue first enter these sites as blood monocytes under physiologic (rather than inflammatory) conditions. These macrophages include macrophages in connective tissue (histiocytes [free macrophages]), liver (Kupffer cells [fixed macrophages]), lung (alveolar macrophages [free macrophages] and intravascular macrophages [fixed macrophages]), lymph nodes (free and fixed macrophages), spleen (free and fixed macrophages), bone marrow (fixed macrophages), serous fluids (pleural and peritoneal macrophages [free macrophages]), and skin (histiocytes [fixed macrophages]). As indicated, during inflammatory conditions monocytes are recruited by inflammatory mediators, such as chemokines, to leave the circulatory system, enter sites of inflammation, and become activated macrophages. This process can occur virtually anywhere in the body and often sets the stage for the development of chronic inflammation.

121

122

Functionally, macrophages are a component of the innate immune system in terms of their role in phagocytosis and cytokine release during the acute inflammatory response. However, macrophages are one of the main triggers of the adaptive immune response because of their ability to process and present antigen and regulate T-cell activity. Monocytes, macrophages, dendritic cells, and other cell types of the chronic inflammatory response will be discussed in greater detail in [Chapter 4](#).

3.9

### CHEMICAL MEDIATORS OF THE ACUTE INFLAMMATORY RESPONSE

Chemical mediators of the acute inflammatory response ([Fig. 3-3](#), [Table 3-3](#), [Appendix 3-1](#)) are often produced as preformed or synthesized molecules in the liver and in neutrophils, basophils, macrophages/monocytes, platelets, mast cells, endothelial cells, smooth muscle cells, fibroblasts, and most epithelial cells. Preformed molecules, such as histamine are transcribed, translated, processed, and stored, often in granules or vacuoles within inflammatory cells. They can be released immediately upon cellular activation and are therefore active in seconds. Other

## Pathologic Basis of Veterinary Disease, 4th Edition

---

molecules, such as most cytokines, adhesion molecules, and prostaglandins, are largely synthesized after an inflammatory cell becomes activated. Endothelial cells, for example, often express low, basal levels of the adhesion molecule ICAM-1, but after the cell becomes activated (by cytokines such as IL-1), they rapidly transcribe the ICAM-1 gene generating ICAM-1 mRNA that is translated into ICAM-1 protein, which is processed, transported, and expressed on the cell surface. This process is somewhat rapid, resulting in ICAM-1 expression within hours; however, it is not nearly as rapid as the release of histamine. Inflammatory mediators originating from plasma proteins, such as kinin, and the coagulation and complement system proteins are constantly secreted by the liver in precursor forms that must be activated via proteolytic cleavage in the circulatory system to their active forms; however, once the proteolytic cleavage is initiated, kinin and complement activity is immediate, similar to histamine.

Inflammatory mediators, whether preformed, synthesized, or derived from plasma, generally bind to receptors on target cells and often activate target cells or cause the target cell to secrete additional inflammatory mediators. In the latter case, the mediators may amplify or suppress secretion by target cells of additional mediators. Once activated and released or secreted, most inflammatory mediators:

- Have short half-lives and quickly decay
- Are enzymatically destroyed by kinases
- Are scavenged by protective mechanisms, such as antioxidants
- Are blocked by endogenous inhibitors such as complement inhibitors

This arrangement provides a check and balance system on the severity of the acute inflammatory response and also can be exploited in the development of drugs to inhibit excessive inflammatory responses. Inflammatory mediators, if excessively unregulated, have the potential to cause severe injury to tissue in and surrounding the acute inflammatory response.

Preformed inflammatory proteins include histamine, serotonin, bradykinin, and tachykinins (substance P and neurokinins). These substances are released during the initial phases of the acute inflammatory response. Mast cells and basophils are the principal sources of histamine and serotonin. Bradykinin is released by leukocytes and vascular endothelial cells, and substance P is released by mast cells, basophils, and C-reactive (sensory) nerve fibers. As indicated, the mediators are rapidly active (in seconds to minutes) and contribute to increased vascular permeability that lasts from minutes to hours.

Histamine rapidly enhances vascular permeability and is one of the earliest recognized mediators of inflammation. Experiments by Sir Thomas Lewis in 1927 and Dale and Laidlaw in 1911 indicated the potential role of histamine and other local mediators in acute inflammation. Histamine is derived from the amino acid histidine through the action of histidine decarboxylase. This enzyme catalyzes the decarboxylation of histidine to histamine and carbon dioxide. Histamine is stored (preformed) in granules of mast cells, basophils, and platelets.

As a mediator of inflammation, major effects of histamine are: (1) vasodilation (active hyperemia) via both H<sub>1</sub> and H<sub>2</sub> receptors, (2) increased microvascular permeability via predominantly the H<sub>1</sub> receptor, (3) neural reflexes, vagal reflexes, bronchial constriction, (4) release of PGF<sub>2</sub>, (5) pain and itching, (6) tachycardia, and (7) eosinophil chemotaxis. The acute vascular effects of histamine are immediate (within minutes) and transient (last about 30 to 90 minutes). Whether histamine has a role in chronic inflammation is speculative, but it may act to modulate the inflammatory response and the reactivity of various leukocytes, including lymphocytes. Antihistamines inhibit

122

123

## Pathologic Basis of Veterinary Disease, 4th Edition

---

binding of histamine to H<sub>1</sub> receptors located on target cells (leukocytes, endothelial cells, and smooth muscle). In addition, eosinophils release histaminases that degrade histamine.

The release of histamine from mast cells is in response to a variety of stimuli including IgE, C3a, C5a, heat, cold, substance P, adenosine triphosphate (ATP), and products from leukocytes, endothelial cells, and platelets. Three histamine receptors of the 7TM receptor family have been described: H<sub>1</sub>, H<sub>2</sub>, and H<sub>3</sub>. Free histamine reacts within minutes with H<sub>1</sub> receptors on venular endothelium to cause contraction and gap formation (cytoskeletal reorganization [actinomyosin filaments]), resulting in increased vascular permeability. Histamine H<sub>1</sub> receptor activation may lead to the production of cytokines and antibodies by T lymphocytes and B lymphocytes, respectively. In addition, H<sub>1</sub> receptors are also found on a variety of blood leukocytes, such as T lymphocytes, B lymphocytes, and monocytes.

Histamine also acts through H<sub>2</sub> receptors found on many cells, such as endothelial cells, gastric epithelial cells, and neurons. The action of histamine on leukocytes is also mediated through histamine H<sub>1</sub> and H<sub>2</sub> receptors. H<sub>3</sub> receptors serve as inhibitory autoreceptors on histamine-containing nerve terminals and regulate the release of neurotransmitters in the central nervous system (CNS) and peripheral nervous system (PNS).

There is substantial overlap of activities by these receptors on many types of cells. Many of the actions of histamine can be mimicked by H<sub>1</sub> and H<sub>2</sub> receptor agonists (a molecule or drug that binds to a receptor and triggers a response by the cell), whereas these actions can be blocked by H<sub>1</sub> and H<sub>2</sub> antagonists, molecules or drugs that block a receptor and prevent a response by the cell. This latter effect is the basis for therapies used in veterinary medicine today. Histamine receptors, for example, are involved in the pathogenesis of allergies, and H<sub>1</sub> receptor antagonists reduce symptoms associated with allergic rhinitis such as sneezing, pruritus, and rhinorrhea (runny nose). In allergic bronchiolitis of cats and horses, H<sub>1</sub> receptor activation results in increased vascular permeability leading to serous inflammation in the bronchi and bronchioles. If this response can be blocked, the effects of allergens can be minimized in affected patients.

Serotonin (5-hydroxytryptamine) is an important preformed vasoactive amine with actions similar to those described previously for histamine. Serotonin is also an important neurotransmitter. Serotonin is found in mast cell granules of rodents and platelets of mammals. Serotonin and histamine are released from platelets after they are activated by the following:

- Aggregation and following contact with collagen in an exposed basement membrane from areas of endothelial necrosis and detached cells
- Thrombin from activation of the coagulation cascade
- Adenosine diphosphate released from injured endothelial cells
- Immune complex activation of the complement cascade (C3a, C5a)

Kinins, such as the tachykinins and bradykinin, are chemical mediators of the acute inflammatory response and also act by modulating the responses of the clotting and complement cascades. Kinin system activation leads ultimately to the formation of bradykinin. Bradykinin, a prototype kinin and a vasoactive peptide, has proinflammatory (makes the disease worse) properties that result in the following:

- Increased vascular permeability

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Vasodilation (venules)
- Increased sensitivity to pain
- Smooth muscle contraction
- Increased arachidonic acid metabolism (stimulation of phospholipase A<sub>2</sub>)
- Hypotension
- Bronchoconstriction

Kinins are formed by two distinct pathways: the plasma kinin pathway and the tissue kinin pathway. The plasma kinin pathway is activated by the contact of a protein complex formed by high molecular weight kininogen (HMWK), factor XI, and prekallikrein with negatively charged surfaces, such as exposed basement membrane. When Hageman factor (factor XII, HF) binds to this surface and interacts with the bound protein complex, there is reciprocal activation/generation of activated Hageman factor (Hfa) and kallikrein (contact activation system). Kallikrein then acts on HMWK to yield bradykinin, an oligopeptide containing nine amino acid residues.

The tissue kinin pathway is generated by the action of tissue kallikrein on a low molecular weight kininogen (LMWK) to produce lysyl bradykinin and finally bradykinin. Tissue kallikrein is chemically and antigenically distinct from plasma kallikrein, although it is capable of acting on either HMWK or LMWK to generate bradykinin. Control of the proinflammatory effects of kinins is through rapid inactivation of bradykinin and kallikrein. Bradykinin is broken down by kininase. Plasma kallikrein is inhibited by C1-INH esterase (serum  $\alpha_2$ -macroglobulin), a member of the serpin family of proteases. This family of proteases forms approximately 20% of the proteins in blood plasma and includes  $\alpha_1$ -antichymotrypsin,  $\alpha_1$ -antitrypsin, and antithrombin III. They act to block proteolytic activity in the clotting and complement systems and thus serve as a regulatory check on these systems.

Tachykinins are a family of vasoactive neuropeptides that includes substance P and neurokinin A and B, which are synthesized by sensory afferent nerve fibers of the lungs and alimentary system. These substances are involved in allergic reactions and asthma. Substance P can induce vasoconstriction, vasodilation, increased permeability changes leading to edema, leukocyte activation, and chemotaxis. Substance P also induces activation and degranulation of mast cells, basophils, and eosinophils and their release of histamine and other inflammatory mediators. The released histamine, in a feedback mechanism, binds the H<sub>3</sub> receptors of nerve fibers and partially inhibits the production of substance P, thus regulating the level of activity. One of the main receptors for substance P, neurokinin-1 receptor (NK-1R), is expressed on a variety of cells including mast cells, epithelial cells, endothelial cells, and macrophages. NK-1R is regulated by substance P expression. Often, increased levels of substance P result in decreased NK-1R expression. The release of substance P from afferent sensory nerve fibers in skin and mucous membranes can also be induced by capsaicinoids such as capsaicin and dihydrocapsaicin. Capsaicinoids are natural compounds present in chile peppers of the genus *Capsicum*, which cause the burning sensation in commercial pepper sprays (less-than-lethal, self-defense weapons). Capsaicin binds the vanilloid receptor-1 of afferent sensory fibers, leading to release of substance P from these fibers. Thus the tachykinins induce inflammatory responses when released by activated and degranulated mast cells, basophils, and eosinophils, and also from stimulated nerve fibers.

123

124

### COMPLEMENT CASCADE

The complement cascade is a unique sequence of molecular events occurring within the vascular system in which inactive plasma proteins synthesized by the liver are activated following tissue injury (Fig. 3-13). This cascade results in the generation of numerous biologically active molecules that have proinflammatory, chemotactic, opsonizing, antigen solubilization, antibody formation, permeability, and microbicidal (cell lysis) effects that are usually beneficial to the animal. A large number of plasma proteins (20 including their cleavage products) make up the complement system and nearly 10% of serum proteins are complement factors. Traditionally divided into the “classical” and “alternative” pathways, activation or “fixation” of complement proteins eventually results in formation of a membrane attack complex (MAC) that perforates the cell membranes of foreign invaders and naïve host cells alike. In the generation of MAC, a variety of complement components are elaborated that have important inflammatory and immune effects.

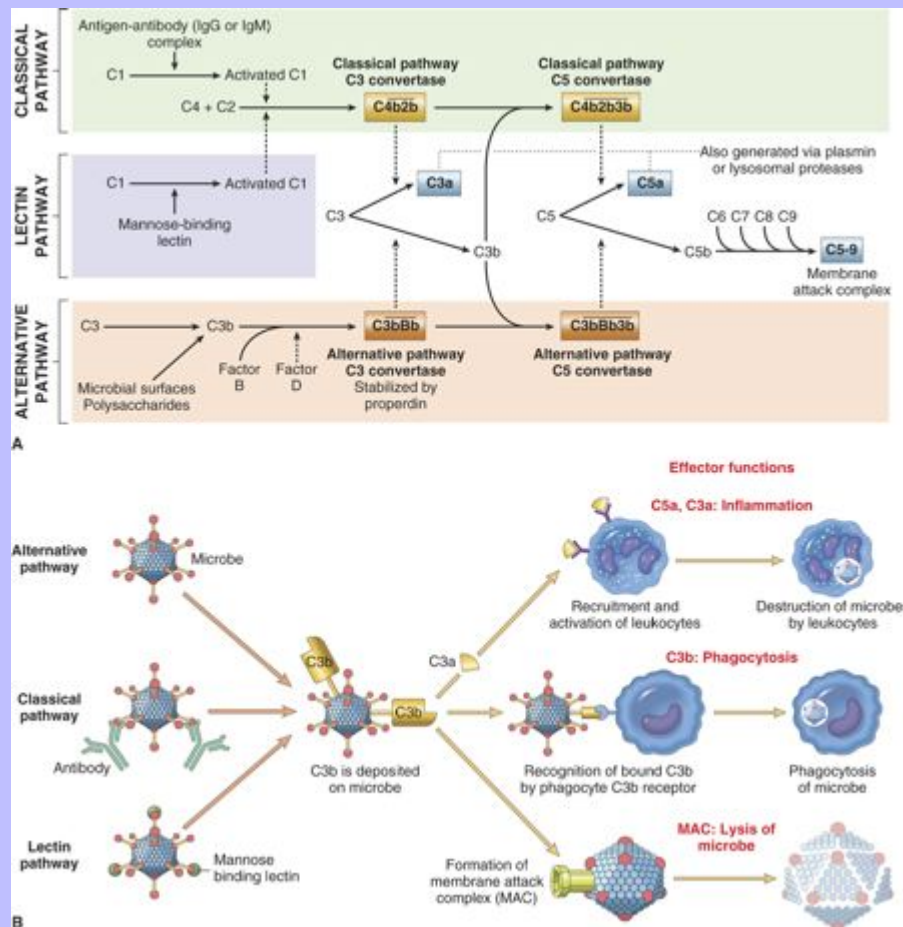

Complement proteins C1 through C9 are inactive components of plasma that are activated by substances including microbial molecules such as endotoxins, aggregated immunoglobulin, complex polysaccharides, and venoms. The critical step in unleashing the biological functions of the complement cascade is activation of C3 through either the classical or alternative complement activation pathways. The classical pathway of the complement cascade can be activated by antibody complexes. Activation occurs when IgG and/or IgM are cross-linked with C1. C1 has three components: C1q, r, and s. C1q binds the Fc regions of IgG and/or IgM and brings C1r, which is proteolytic, into proximity to C1s, which is cleaved; through interactions with C4 and C2, and leads to the formation of classical pathway C3 convertase (C4b2a) and the eventual formation of classical pathway C5 convertase (C4b2a3b). Classical pathway C3 convertase converts C3 to C3a, and classical pathway C5 convertase converts C5 to C5a.

The alternative pathway is initiated by products from microorganisms including LPS (lipopolysaccharide) from gram-negative bacteria and polysaccharides from fungal cell walls. In addition, other activated plasma proteins, including kallikrein, plasmin, and activated factor XII, can cleave C3 resulting in its activation to C3b. C3b combines with factor B and, coupled with factor D activity, forms the alternative pathway C3 convertase (C3bBb). Alternative pathway C3 convertase converts C3 to C3b. C3b combines with alternative pathway C3 convertase to form alternative pathway C5 convertase (C3bB3b), which converts C5 to C5a. Because the alternative pathway can be activated by clotting and kinin factors, once the clotting or the kinin systems are activated, complement activity follows and vice versa. Therefore the clotting, kinin, and complement systems are closely interactive, and often activation of one system leads to activation of others (Fig. 3-14).

C3a increases vascular permeability by inducing histamine release from mast cells. C5a, once formed, is released into the inflammatory exudate and behaves as an anaphylatoxin (a molecule that causes the release of histamine and other chemical mediators from mast cells or basophils), a chemoattractant for leukocytes, and an inducer of adhesion molecule expression by endothelial cells. C3b is an important opsonin and enhances neutrophil phagocytosis. The plasma enzyme carboxypeptidase can degrade both C3a and C5b.

A MAC results from the cleavage of C5 by C5 convertase, leading to the formation of C5a and C5b. C5b serves as the anchor for the assembly of a single molecule composed of C6, C7, and C8. This MAC (C5b with C6, C7, C8) facilitates polymerization of C9 (up to 18 molecules of C9) into a tube that is inserted into the lipid bilayer of the plasma membrane of, for example, a bacterium. A channel is formed through the cell membrane allowing the passage of ions, small molecules, and water into the bacterium by osmosis. Bacterial lysis ensues. This process can also injure naïve host cells, such as occurs in hemolytic anemias.

Fig. 3-13 **A**, Components and pathways of the complement cascade. **B**, Effector functions of the complement system. *IgG*, Immunoglobulin G; *IgM*, immunoglobulin M. ### 3.9.2 ARACHIDONIC ACID METABOLITES

When cells are injured by inflammatory stimuli or other chemical mediators of inflammation, their cell membrane lipids are rapidly rearranged to create a variety of biologically active lipid mediators derived from arachidonic acid. Arachidonic acid metabolites are lipid-derived autocrine (acting as a local hormone) mediators of inflammation that serve as intracellular and extracellular signals influencing the coagulation cascade and mediating nearly every step of the acute inflammatory response (Fig. 3-15). Effects are short-lived because these lipid metabolites decay rapidly or are destroyed by enzymes. Arachidonic acid metabolites include

## Pathologic Basis of Veterinary Disease, 4th Edition

prostaglandins, leukotrienes, and lipoxins and encompass the cyclooxygenase (COX) and lipoxygenase pathways.

**Fig. 3-14 Interrelationships between the four plasma mediator systems triggered by activation of factor XII (Hageman factor).** Note that thrombin induces inflammation by binding to protease-activated receptors (PARs) (principally PAR-1) on platelets, endothelium, smooth muscle cells, and other cells. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Arachidonic acid (eicosatetraenoic acid) is an essential 20-carbon fatty acid derived from linoleic acid, which is present in plasma membranes of dietary red meats. It is an integral component of esterified membrane phospholipids and serves as the major precursor for eicosanoids. Eicosanoids are synthesized by two important classes of enzymes: (1) cyclooxygenases and (2) lipoxygenases, and their respective products (eicosanoids) are: (1) prostaglandins and thromboxanes and (2) leukotrienes and lipoxins. These molecules are synthesized in endothelial cells, leukocytes, and platelets and principally exert their biologic effects on vascular and airway smooth muscle cells, endothelial cells, and platelets during the acute inflammatory response.

Arachidonic acid is released from membrane phospholipids of many cell types, but particularly endothelial cells and leukocytes, through the action of cytoplasmic phospholipase A<sub>2</sub> (cPLA<sub>2</sub>) and to a lesser degree, soluble (extracellular) phospholipase A<sub>2</sub> (sPLA<sub>2</sub>). This outcome occurs in response to physical and chemical stimuli including C5a. cPLA<sub>2</sub> is translocated from the endoplasmic reticulum to plasma membrane when intracellular calcium concentrations increase. The activity of sPLA<sub>2</sub> also requires the participation of calcium; however, its contribution to the formation of intracellular arachidonic acid varies among the different cell types when

## Pathologic Basis of Veterinary Disease, 4th Edition

compared with that of cPLA<sub>2</sub>. Membrane phospholipids contain a glycerol backbone attached to which is often a saturated fatty acid at the sn-1 position, an unsaturated fatty acid at the sn-2 position, and a base at the sn-3 position. Arachidonic acid is often in the sn-2 position and released by cPLA<sub>2</sub> or sPLA<sub>2</sub> to become free arachidonic acid.

126

127

**Fig. 3-15 Key inflammatory mediators derived from the plasma membrane.**

Cytoplasmic phospholipase A<sub>2</sub> (cPLA<sub>2</sub>) activity on the plasma membrane leads to free arachidonic acid (AA) and lysophosphatidylcholine (LPC). Arachidonic acid metabolites include prostaglandins and leukotrienes, and LPC is a substrate for platelet-activating factor (PAF). The type of prostaglandin formed by a cell is dependent on the cell type. Platelets, for example, form thromboxane, whereas endothelial cells form prostacyclin. Leukotrienes are formed by leukocytes. Inhibitors specific to the various enzymes or products are listed in red. COX, Cyclooxygenase; EETs, epoxyeicosatrienoic; FLAP, 5-lipoxygenase-activating protein; HETE, hydroxyeicosatetraenoic acid; LOX, lipoxygenase; LTA<sub>4</sub>, LTB<sub>4</sub>, LTC<sub>4</sub>, LTE<sub>4</sub>, leukotrienes A<sub>4</sub>, B<sub>4</sub>, C<sub>4</sub>, and E<sub>4</sub>, respectively; LTA<sub>4</sub>H, leukotriene A<sub>4</sub> hydrolase; LTC<sub>4</sub>S, leukotriene C<sub>4</sub> synthase; PGD<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2</sub>, PGH<sub>2</sub>, PGI<sub>2</sub>, prostaglandins D<sub>2</sub>, E<sub>2</sub>, F<sub>2</sub>, H<sub>2</sub>, and I<sub>2</sub>, respectively; PGHS, prostaglandin H synthase; PS, polysaccharides; sPLA<sub>2</sub>, soluble phospholipase A<sub>2</sub>; TXA<sub>2</sub>, thromboxane A<sub>2</sub>. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

Free arachidonic acid is metabolized in one of three pathways: (1) the COX pathway for the formation of prostaglandins and thromboxanes; (2) the lipoxygenase pathway for the formation of leukotrienes and lipoxins; and (3) the cytochrome p450 pathway for the formation of epoxyeicosatrienoic acids (HPETE and HETE). There are three COX isoenzymes—COX-1, COX-2, and COX-3—that are actually components of prostaglandin H synthase and work in concert with a peroxidase heme group. The COX-1 isoenzyme is constitutively expressed, is present in almost all tissues, and is considered a housekeeping enzyme with physiologic roles in hemostasis and gastroprotection. COX-2 isoenzyme expression is induced by exogenous and endogenous stimuli and occurs locally in sites of inflammation. It is present in leukocytes, endothelial cells of blood vessels, and synovial fibroblasts. COX-3 isoenzyme is a splice variant of COX-1 (and also termed COX-1b or COX-1v). It is present in greatest abundance in the cerebral cortex of dogs and human beings and is also detected in human aortas and rodent cerebral endothelia, heart, kidney, and neuronal tissues.

127

128

### 3.9.3

#### PROSTAGLANDIN FORMATION AND INHIBITION

Arachidonic acid metabolites from COX isoenzymes induce an intermediate prostaglandin,  $\text{PGH}_2$  that is converted into at least five metabolites ( $\text{PGD}_2$ ,  $\text{PGF}_2$ ,  $\text{PGE}_2$ ,  $\text{PGI}_2$ , and  $\text{TXA}_2$ ) by prostanoid synthase enzymes unique for each of these five metabolites. The relative concentration of each of these five types of prostaglandins synthesized following stimulation depends on the cell type stimulated. For example,  $\text{PGI}_2$ —a thromboresistant prostaglandin termed prostacyclin—is produced by endothelial cells via  $\text{PGI}_2$  (prostacyclin) synthase, whereas  $\text{TXA}_2$ —a thrombogenic prostaglandin termed thromboxane—is produced by platelets via  $\text{TXA}_2$  (thromboxane) synthase.  $\text{PGD}_2$  is the major prostanoid produced by mast cells;  $\text{PGE}_2$  is the major prostanoid produced by epithelial cells, fibroblasts, and smooth muscle cells. These factors inhibit ( $\text{PGI}_2$ ), induce ( $\text{TXA}_2$ ) coagulation/thrombosis, or affect vascular permeability ( $\text{PGD}$  and  $\text{PGE}$ ).

Aspirin, indomethacin, ibuprofen, and naproxen are COX-1 inhibitors (Fig. 3-15). Aspirin, naproxen, and ibuprofen also inhibit COX-2, as do the highly selective COX-2 inhibitor drugs celecoxib, rofecoxib, valdecoxib, lumiracoxib, and etoricoxib. Acetaminophen inhibits COX-3 in dogs; however, acetaminophen's activity in human beings and rodents is less clear. Because COX-3 is present in greatest abundance in the cerebral cortex and acetaminophen crosses the blood-brain barrier (unlike other NSAIDs), these observations were initially thought to explain why acetaminophen was sometimes more effective for treating headaches and pain relief and less effective in inhibiting inflammation in the body. Although this may be the case in dogs, the mechanistic basis of acetaminophen's activity in human beings is not fully understood at this time. Acetaminophen may inhibit COX-2 to a minor degree and also slightly inhibit COX-3 (COX-1b), and yet have other activity/activities. Much of the antiinflammatory effect of corticosteroids is due to their inhibition of phospholipase  $\text{A}_2$ , the enzyme that releases arachidonic acid from membrane phospholipids. Corticosteroids signal the cell to synthesize a polypeptide known as lipocortin (lipomodulin), which then acts to inhibit phospholipase  $\text{A}_2$ . Therefore the antiinflammatory effect of corticosteroids is delayed. A variety of other natural and synthetic compounds can inhibit phospholipase  $\text{A}_2$ .

### 3.9.4

#### LEUKOTRIENE FORMATION AND INHIBITION

In leukocytes, arachidonic acid can also be metabolized through the 5-lipoxygenase pathway to form leukotrienes and lipoxins (Fig. 3-15). 5-Lipoxygenase works in concert with 5-lipoxygenase activating protein as an arachidonic acid binding protein, which optimizes the proximity of 5-lipoxygenase to interact with arachidonic acid. The complex formed by 5-lipoxygenase and 5-lipoxygenase activating protein called

## Pathologic Basis of Veterinary Disease, 4th Edition

5-HPETE (hydroperoxyeicosatetraenoic acid) is converted to an intermediate complex, leukotriene  $A_4$ , which is subsequently converted to either leukotriene  $B_4$  or leukotriene  $C_4$ , via leukotriene  $A_4$  hydrolase or leukotriene  $C_4$  synthetase, respectively. Leukotriene  $C_4$  synthetase is a glutathione transferase, and once leukotriene  $C_4$  is secreted from a cell, it is metabolized to leukotriene  $D_4$  and leukotriene  $E_4$  by sequential removal of the glutathione, glutamic acid, and glycine moieties.

The major effects of the leukotrienes include: (1) increased vascular permeability, (2) chemotaxis for leukocytes, and (3) vasoconstriction, all of which exacerbate the acute inflammatory response. Neutrophils produce primarily leukotriene  $B_4$ , which is one of the most potent chemotactic factors for neutrophils and macrophages. It also stimulates leukocytes to release their lysosomal contents. Mast cells and eosinophils produce primarily leukotriene  $C_4$ , and the group of leukotrienes—leukotriene  $C_4$ , leukotriene  $D_4$ , and leukotriene  $E_4$ , formerly known as “slow reacting substance”—causes intense vascular leakage from the venules. Macrophages produce both leukotriene  $B_4$  and leukotriene  $C_4$ . In addition to the leukotrienes, 5-HPETE and its end product 5-HETE (hydroxyeicosatetraenoic acid) are highly chemotactic for neutrophils and macrophages.

Lipoxins, secreted primarily by platelets, are also produced from arachidonic acid via the lipoxygenase pathway. Platelets cannot form lipoxins directly, but through cell-to-cell interactions with leukocytes and the transfer of arachidonic acid metabolites to platelets, cooperation between different cells types can result in the formation of eicosanoids via transcellular biosynthesis. Neutrophils can transfer their leukotriene  $A_4$  to platelets. Platelets contain 12-lipoxygenase, which converts the neutrophil derived and transferred leukotriene  $A_4$  to lipoxin  $A_4$  and lipoxin  $B_4$ . Lipoxins have proinflammatory and antiinflammatory effects and appear to counteract the effects of leukotrienes. They stimulate macrophage adhesion to endothelial cells in blood vessels, but inhibit neutrophil adhesion and chemotaxis. Lipoxin  $A_4$  causes vasodilation and dampens the actions of leukotriene  $C_4$ -induced vasoconstriction.

The 5-lipoxygenase pathway can be inhibited by a variety of new chemical agents (5-lipoxygenase inhibitors and leukotriene receptor antagonists) (Fig. 3-15). In addition, eosinophils release arylsulfatase from granules, which inactivates leukotrienes.

128

129

### 3.9.5

#### OMEGA 3 FATTY ACIDS (FISH OILS) AND INHIBITION OF EICOSANOID ACTIVITY

Many studies have demonstrated that omega 3 fatty polyunsaturated fatty acids, which are in high concentrations in certain fish, can reduce inflammatory responses, particularly prostaglandin and leukotriene activity (Fig. 3-15). This effect occurs because omega 3 fatty acids, when acted upon by phospholipase A and subsequent enzymes, form the “3” series of prostaglandins (thromboxane  $A_3$ ) and the “5” series of leukotrienes ( $LTB_5$ ) instead of the “2” series of prostaglandins (thromboxane  $A_2$ ) and the “4” series of leukotrienes ( $LTB_4$ ), which occur with omega 6 fatty acids. The “3” and “5” series of prostaglandins and leukotrienes derived from omega 3 fatty acids are less biologically active than their omega 6 series counterparts. Roughly two thirds of the polyunsaturated fatty acids in the body have an omega 6 structure; the remaining have an omega 3 structure. This two-thirds to one-third ratio can be altered by consumption of diets high in fish oils and thereby result in more omega 3 in the tissue and less active prostaglandin and leukotriene products.

### 3.9.6 PLATELET-ACTIVATING FACTOR

PAF is another potent molecule of phospholipid origin derived from cell membranes of platelets, basophils, mast cells, neutrophils, macrophages, and endothelial cells. PAF has potent pathophysiologic effects and contributes to inflammation, endotoxic shock, and allergic reactions (asthma) through vasoconstriction, bronchoconstriction, platelet aggregation, and leukocyte adhesion, chemotaxis, and degranulation. However, at low concentrations (experimentally induced), PAF can cause vasodilation and increased vascular permeability. PAF also contributes to the inflammatory response by increasing the oxidative burst in neutrophils following phagocytosis of bacteria and enhances the synthesis of eicosanoids by leukocytes. PAF can also cause platelet aggregation followed by release of serotonin and histamine when mast cells are degranulated in response to PAF released during IgE-mediated hypersensitivities in the lung. Thus platelet aggregation can increase vascular permeability in acquired immunologic responses and result in inflammation.

LysoPAF acetyltransferase (lysoPAF-AT) and PAF-synthesizing phosphocholinetransferase (PAF-PCT) are two enzymes that control the final synthesis of PAF from lipid membranes and thus promote PAF production. PAF mediates its effects on target cells through a single G protein-coupled receptor. These receptors have been identified on endothelium, neutrophils, eosinophils, macrophages, smooth muscle, and glial cells in the brain, and thus to a certain extent an autocoid regulatory system exists. PAF activity is reduced/regulated by PAF acetylhydrolase, which is expressed in the previously listed target cells. PAF acetylhydrolase degrades PAF through hydrolysis of its acetate moiety in the *sn*-2 position of glycerol and thus inhibits the proinflammatory activity of PAF. PAF acetylhydrolase is thus potentially an enzyme that could be used for the development of drugs to reduce inflammatory responses.

### 3.9.7 CYTOKINE FAMILY

#### 3.9.7.1 OVERVIEW

Cytokines are a group of proteins produced by many cell types including lymphocytes (lymphokines), macrophages (monokines), endothelial cells, neutrophils, basophils, mast cells, eosinophils, epithelial cells, and connective tissue cells ([Appendix 3-1](#)). Their primary purpose is to modulate, via enhancement or suppression, the functional expression of other cell types during the inflammatory response. Chemokines are produced from almost all cell types and are cytokines that promote leukocyte chemotaxis and migration across capillaries and postcapillary venules. Cytokines also play major roles in: (1) hematopoiesis, including granulopoiesis by cytokines, such as IL-3 and G-CSF; and (2) adaptive immunity, such as the proliferation of lymphocytes by cytokines, including IL-2, and activation of T<sub>H</sub>1 or T<sub>H</sub>2 responses by IL-10 and IL-12, respectively. More than 29 major cytokines are now recognized, which have been organized into the following categories according to their principal functional activities:

- Hematopoietic growth factors, including IL-3, GM-CSF, possibly IL-9, IL-11, and stem cell factor
- Inflammatory mediators, which induce acute phase reactants and natural immunity (IL-1, IL-6, TNF)
- Chemotactic cytokines (IL-8)
- T-cell proliferation, activation, and differentiation cytokines (ILs 2, 4, 5, 7, 9, 10, 12 on up to IL-29)

Concerning T-lymphocyte activity, there are cytokines and proteins that exert lymphocyte regulatory activity (interferon [IFN]- $\gamma$ , TGF- $\beta$ ). Of particular importance in allergic disease is the recognition of the control of dendritic cells by T-lymphocyte regulatory cells that release IL-4 and IL-10, and two lineages of T-lymphocyte helper cells (T<sub>H</sub>1 and T<sub>H</sub>2). Dendritic cells (part of the monocyte-macrophage system) are cells of the adaptive immune system. They are present in tissue in contact with the environment and include Langerhans' cells of the skin and dendritic cells of the mucosal surfaces of the respiratory and alimentary systems. They are sentinel cells constantly monitoring for and phagocytosing microbes and foreign materials. In cooperation with lymphocytes and macrophages in lymphoid tissue, they act as antigen presenting cells to activate T helper cells and cytotoxic T cells and B cells. The T<sub>H</sub>1 lineage, normally driven by IL-12 and IFN- $\gamma$ , induces cell-mediated immune responses within specific diseases, such as the granulomatous inflammatory response to mycobacterial infections, whereas the T<sub>H</sub>2 cells induce humoral responses and humoral-related diseases, such as asthma and atopy.

129

130

Biochemically, cytokines can be divided into type I and type II cytokines. Type I cytokines have four  $\alpha$  helix units. Type II cytokines have six  $\alpha$  helix units and are likely derived from a single ancestral gene. Type I and II cytokines bind receptors specific for the I and II ligand structures. Despite the similarities within type I and type II cytokines and their receptors, there is still much diversity in structure and function of cytokines within each type.

### 3.9.7.2

#### CYTOKINE RECEPTORS AND SIGNALING

Cytokine activity can be altered in several ways, usually via binding to and activating cytokine receptors. Briefly, there are class I cytokine receptors (receptors for IL-2 through IL-9, IL-11 through ILs 13, 15, 21, 23, 27, erythropoietin (EPO), G-CSF, GM-CSF, leptin, and others) and class II cytokine receptors (receptors for IFN- $\alpha$ , IFN- $\beta$ , IFN- $\gamma$ , and ILs 10, 19, 20, 22, 24, 26, 28, and 29). EPO agonists are commonly used for patients with anemia and are drugs abused by endurance athletes, such as marathoners, cross-country skiers, and cyclists. Other G-CSF agonists, such as Neupogen (Amgen Inc., Thousand Oaks, Calif), increase granulopoiesis and are commonly used for cancer patients with decreased blood neutrophil levels (neutropenia) secondary to chemotherapy. Agonists have also been developed for IFN- $\beta$ .

Many cytokine receptors, including those for the interferons IL-2 through IL-7, IL-11, IL-13, erythropoietin, and GM-CSF, activate the JAK/STAT signaling pathway (Fig. 3-16). JAK stands for Janus kinase, and STAT is an abbreviation for signal transducer and activator of transcription. Members of the JAK family are cytoplasmic protein tyrosine kinases physically associated with ligand-bound receptors. JAK phosphorylates amino acids in a protein on STAT, and STAT dimers (a molecule consisting of two identical simpler molecules) enter the nucleus to bind DNA and induce transcription and the expression of specific gene products and cellular responses to activation. There are three isoforms of JAK (JAK1 to JAK3) and a fourth JAK family member TYK2. All of these have slightly different activities depending on the stimulus. JAK1, for example, is integral to lymphocyte development, whereas JAK2 mediates erythropoiesis. There are several isoforms in the STAT family including STAT 1 to 6, which also have subtle signaling differences. STAT 1 and 2 are especially involved with interferon signaling, STAT 3 mediates responses to pathogens, STAT 4 is involved with T<sub>H</sub>1/IL-12 activity, STAT 5 mediates cell growth and natural killer (NK) growth, and STAT 6 mediates T<sub>H</sub>2 responses. Suppressors of cytokine signaling (SOCS) are signaling proteins that inhibit activity of some cytokines whose receptors induce the JAK/STAT pathway of signaling through the inhibition of JAK. Protein tyrosine phosphatases (PTPs) such as SHP2 (SH2-domain-containing PTP) can inhibit JAK and STAT. Phosphorylated STAT proteins in the nucleus can be inhibited by PIAS (protein inhibitor of activated signal transducer and activator of transcription) proteins as well. These proteins

## Pathologic Basis of Veterinary Disease, 4th Edition

---

regulate the activity of cytokine activity on cells, and as discussed later, these pathways may be potentially useful as a mechanism to target and inhibit specific components of the acute inflammatory response with existing or newly developed antiinflammatory drugs.

TNF- $\alpha$  receptors are trimers of three identical cell surface transmembrane proteins. Binding of the receptor triggers phosphorylation of I kappa B (IKB) and thereby allows release of IKB from nuclear factor (NF) kappa B in the cytosol. IKB becomes ubiquitinated and degraded, and NF kappa B moves to the nucleus, where it binds promoter and enhancer regions of DNA of more than 60 genes, including genes for IL-1 and other cytokines, and genes for cell proliferation, cell adhesion, and angiogenesis. TNF can also bind receptors that lead to apoptosis.

Cytokine activity can also be inhibited. Nonspecific inhibitors include corticosteroids, aspirin, and ibuprofen. More precisely, “molecular” inhibitors can inhibit cytokine activity through anticytokine antibodies, such as anti-TNF MAb (Remicade, Centocor Inc., Horsham, Penn), or the blockage of receptors, such as soluble TNF-R (Embrel, Wyeth Pharmaceuticals, Madison, NJ). Specific inhibitors are also under development for cytokine receptors including SOCS and PTP.

### 3.9.7.3

#### CYTOKINES THAT REGULATE NATURAL KILLER CELL FORMATION AND ACTIVITY

IL-21 has been recently described and appears to regulate differentiation and apoptotic death induced by NK cells. NK cells are specialized to kill certain types of target cells, such as tumor cells or cells infected with viruses that may be the underlying cause of inflammation. NK cells are considered lymphocytes but do not express T-cell receptors or CD3, an antigen expressed on the surface of T lymphocytes; however, they do have an intrinsic ability to engage in perforin-mediated killing. NK cells secrete specialized granules that contain potent cytotoxic molecules, such as perforin, which cause lysis of target cells on contact. Inactive NK cells can be stimulated by Flt-3 ligand, a hematopoietic cytokine that stimulates proliferation of dendritic cells and antitumor immune responses, and also by IL-4, IL-12, IL-15, and IL-21. Once activated, IL-21 induces NK cell differentiation and upregulation of CD16, the low affinity IgG receptor necessary for antibody-dependent cellular cytotoxicity, and also NK release of IFN- $\gamma$  required for macrophage and dendritic cell activation. Finally, IL-21 initiates a delayed apoptotic program for death of the differentiated NK cell and prevents recruitment of uninvolved NK cells.

130

131

**Fig. 3-16 Several families of cytokines activate the JAK/STAT (Janus kinase/signal transducer and activator of transcription) pathway.** The STAT class of proteins function both as a signal transducer and transcription activator. Activation of STAT involves dimerization and phosphorylation by JAK, a tyrosine kinase. Signaling by JAK/STAT proteins is regulated by proteins such as the SOCS (suppressor of cytokine signaling). JAK/STAT signaling leads to transcription of genes that drive inflammatory responses, including cell activation, immune regulation, and cell proliferation. *CIS*, Cytokine-inducible SH2 domain-containing protein; *PIAS*, protein inhibitor of activated signal; *PTPs*, protein tyrosine phosphatases; *TYK*, tyrosine kinase (of the JAK family). (Modified from Leonard W: Nat Rev Immunol 1:200-208, 2001.)

### 3.9.7.4 PROTEINS WITH CYTOKINE-LIKE FUNCTIONS

#### 3.9.7.4.1 High Mobility Group Box Protein-1

High mobility group box protein-1 (HMGB-1) is a nonhistone nuclear protein that has cytokine-like functions. It was first described as a nonhistone chromosome protein transcription and replication regulator, a nucleosome stabilizer, a mediator of cell differentiation, a regulator of metastasis by neoplastic cells, and a mediator of neurite outgrowth. Now HMGB-1 is recognized as a mediator of endotoxemia, sepsis, inflammation, and sickness behavior (nausea and the feeling of being ill or sick). IL-1, TNF, and interferons induce macrophages to secrete HMGB-1 and lysophosphatidylcholine; the latter molecule plays a key role in the response of monocytes to LPS released from gram-negative bacteria. HMGB-1, an advanced glycosylation end product, binds macrophage RAGE (receptor for advanced glycosylation end products), which further induces IL-1, TNF- $\alpha$  and IFN- $\gamma$  release. HMGB-1 and cytokines—such as IL-1, TNF, IL-6—and prostaglandins such as PGE<sub>2</sub> are involved with hypothalamic function in food aversion, hypophagia, anorexia, weight loss, and sickness behavior (see later discussion of febrile response) and serve to amplify the inflammatory response.

131

132

### 3.9.7.5 CHEMOKINES

Chemokines, released in response to inflammatory stimuli, are secreted proteins that induce neutrophil, macrophage, and lymphocyte chemotaxis into inflammatory exudates. They also activate inflammatory cells, induce antiviral activity, regulate immune responses, and induce hematopoiesis, angiogenesis, and cell growth. Chemokines are produced by all nucleated cells in the body, including epithelial cells, fibroblasts, macrophages, mast cells, keratinocytes, dendritic cells, and endothelial cells. Leukocytes secrete all types of chemokines, except for fractalkine (used for monocyte chemotaxis), which is produced by nonhematopoietic cells such as vascular endothelial cells.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 3-8 Name, Abbreviation, and Common Name of Chemokines

Name	Abbreviation	Common Name
CCL1	TCA	T-lymphocyte activation (I-309)
CCL2	MCP-1	Macrophage chemotactic protein-1
CCL3	MIP-1- $\alpha$	Macrophage inflammatory protein-1- $\alpha$
CCL4	MIP-1- $\beta$	Macrophage inflammatory protein-1- $\beta$
CCL5	RANTES	Regulated on activation, normal T lymphocytes expressed and secreted
CCL7	MCP-3	Macrophage chemotactic protein-3
CCL8	MCP-2	Macrophage chemotactic protein-2
CCL11		Eotaxin
CCL12	MCP-5	Macrophage chemotactic protein-5
CCL13	MCP-4	Macrophage chemotactic protein-4
CCL17	TARC	Thymus and activated regulated cytokine
CCL19	MIP-3- $\beta$	Macrophage inflammatory protein-3- $\beta$
CCL20	LARC/MIP-3- $\alpha$	Liver and activation-regulated chemokine/Macrophage inflammatory protein-3- $\alpha$
CCL21	SLC	Secondary lymphoid organ chemokine
CCL22	MDC	Macrophage-derived chemoattractant
CCL24	unknown	Eotaxin-2
CCL26	unknown	Eotaxin-3
CXCL1	Gro- $\alpha$	Growth-related oncogene- $\alpha$
CXCL2	Gro- $\beta$	Growth-related oncogene- $\beta$
CXCL3	Gro- $\gamma$	Growth-related oncogene- $\gamma$
CXCL5	ENA-78	Epithelial neutrophil-activating peptide-78
CXCL6	GCP-2	Granulocyte chemotactic protein-2
CXCL8	IL-8 (NAP-1)	Interleukin-8
CXCL9	MIG	Monokine induced by $\gamma$ -interferon
CXCL10	IP-10	Interferon-inducible protein
CXCL11	ITAC	Interferon-inducible T lymphocyte $\alpha$ chemoattractant
CXCL12	SDF-1	Stromal derived factor-1
CXCL13	BCA-1/BLC	B lymphocyte attracting chemokine
CXCL14	BRAK	Breast and kidney expressed chemokine
CXCL16		

Chemokines can be classified based on biochemical structure (position of their cysteine residues) or by the functional behavior they induce (inflammatory or homing). Structural classification of chemokines is based on their primary amino acid structure depending on their cysteine residues that induce secondary folding (Table 3-8). Most numerous are the chemokines in: (1) the CC family, which bind the CCR (receptor); (2) the CXC family, which bind the CXCR, (3) the C chemokine lymphotoxin, which binds CR, and (4) the CX3C chemokine fractalkine, which binds CX3CR.

The functional classification of chemokines includes inflammatory chemokines or homing chemokines. Inflammatory chemokines (IL-8, GCP-2, ENA-78, Gro, NAP-2, IP-10, Mig, I-Tac, RANTES, MIP- $\alpha$  and MIP- $\beta$ , MCP-2,3, HHC-1, MCP 1 to 5, and eotaxins 1 to 3) are expressed by resident cells and infiltrating leukocytes in response to cytokines, bacterial toxins, and other agents during the acute inflammatory response. Receptors for these chemokines include CXCR1, 2, 3 and CCR1, 2, 3, and 5; these receptors often bind several different chemokines (Table 3-9). Chemokines for leukocyte homing are generally produced constitutively in lymphoid tissue. Receptors for these chemokines are usually present on lymphocytes and dendritic cells, and they typically bind only one or maybe two chemokines. The expression of receptors by these cells varies with the state of cellular differentiation, thereby preventing immature cells from entering the wrong location. For example, naïve cells express CCR1-10 and CXCR1-3,5 as well as CR1 and CX3CR1;

132

133

## Pathologic Basis of Veterinary Disease, 4th Edition

memory T lymphocytes express CCR 8-10, CXCR1,2,4,5, and CR1 but do not express CCR1-7, CXCR3, and CXCR31. Commonly studied chemokines include IL-8, MCP-1 (macrophage chemotactic protein), RANTES, IP-10, SDF-1, and eotaxin.

**Table 3-9 Chemokine Ligands of the C-C and C-X-C Families and Their Receptors**

Family	Ligand	Receptor
C-C	CCL 3, 7, 9, 15, 16, 23	CCR1
	CCL 2, 7, 8, 12, 13	CCR2
	CCL 5, 7, 8, 11, 13, 24, 26	CCR3
	CCL 17, 22	CCR4
	CCL 3, 4, 5	CCR5
	CCL 20	CCR6
	CCL 19, 21	CCR7
	CCL 1, 16, 17	CCR8
	CCL 25	CCR9
	CCL 27, 28	CCR10
	CCL 2, 7, 8, 11, 12, 13	CCR11
C-X-C	CXCL 1, 6, 7, 8	CXCR1
	CXCL 1, 2, 3, 5, 6, 7, 8	CXCR2
	CXCL 9, 10, 11	CXCR3
	CXCL 12	CXCR4
	CXCL 13	CXCR5
	CXCL 14	Unknown
	CXCL 16	CXCR6

3.9.7.6

### CHEMOKINE RECEPTORS AND SIGNALING

Chemokines are the only cytokines that bind G protein–coupled seven transmembrane (7TM) spanning receptors, and although chemokines are relatively small (8 to 10 kDa), they are somewhat large for the 7TM receptor family, which also binds larger proteins such as histamine, dopamine, and serotonin. Once bound, the 7TM receptor activates a G protein, which initiates production of second messengers, most commonly cyclic adenosine monophosphate (cAMP) and inositol 1,4,5-triphosphate IP<sub>3</sub>. cAMP and IP<sub>3</sub>, in turn, phosphorylate enzymes and stimulate the release of calcium. Enzymatic activity induced by cAMP activates the transcription factor CREB (cAMP response element binding protein). Chemokine receptors bound by ligand are endocytosed and either recycled or degraded by the cell.

Experimentally, chemokines can be inhibited at several stages: (1) inhibition of interaction between the ligand and the glycosylated molecules on the cell surface, (2) inhibition of ligand/receptor binding, (3) inhibition of receptor activity, and (4) inhibition of cell signaling. The development of new drugs to treat specific aspects of inflammatory diseases will likely target one or all of these pathways in the chemokine cascade.

3.9.8

### OXYGEN-DERIVED FREE RADICALS AND NITRIC OXIDE

Free radicals such as superoxide anion, hydroxy radical, and nitric oxide derivatives result in lipoperoxidation of phospholipid membranes, damage to DNA molecules resulting in strand breaks and adduct formation, and oxidation of signaling molecules—thus affecting (increasing or decreasing) cytokine and other signaling pathways. The oxidative radicals can: (1) injure vascular endothelial cells, leading to increased vascular

## Pathologic Basis of Veterinary Disease, 4th Edition

permeability; (2) inactivate antiproteases, such as  $\alpha_1$ -antitrypsin, resulting in damage to extracellular matrix proteins; (3) enhance cytokine expression secondary to signaling changes and cell damage; (4) activate endothelial cells and increase adhesion molecule expression; and (5) increase the formation of chemotactic factors (LTB<sub>4</sub>). They can also inactivate neurotransmitters (adrenaline and noradrenaline), leading to hypotension.

Oxygen-derived free radicals are released from neutrophils and macrophages following exposure to chemokines and immune complexes, and after phagocytosis by the leukocyte. They damage cells through peroxidation of cell membrane lipids, cross-linking of proteins, cleaving glycoconjugates, directly damaging DNA phosphate backbone and bases, and inducing the formation of DNA adducts. Fortunately, the body has antioxidants that are: (1) enzymatic, such as superoxide dismutase (SOD isoforms 1, 2, and 3), catalase, and glutathione peroxidase; (2) nonenzymatic, such as ceruloplasmin, transferrin, and melatonin; and (3) nonenzymatic dietary substances, such as vitamins A, C, and E and lycopenes, flavonoids, genistein, and reserpines. All of these minimize the damage to tissue caused by free radicals.

Nitric oxide is a chemical mediator of inflammation that causes vasodilation by relaxing vascular smooth muscle cells. In response to injury and inflammatory stimuli, nitric oxide derivatives are synthesized by endothelial cells, macrophages, and specific populations of neurons in the brain from l-arginine, molecular oxygen, NADPH, other cofactors, and the enzyme nitric oxide synthase (NOS). There are three forms of nitric oxide synthase that mediate nitric oxide formation: neuronal (nNOS), inducible (iNOS), and endothelial (eNOS). In addition to its vasodilatory activities, nitric oxide inhibits platelet aggregation and adhesion, inhibits mast cell-induced inflammation, oxidizes lipids and other molecules, and regulates leukocyte chemotaxis.

133

134

3.9.9

### RECEPTORS FOR EXOGENOUS AND ENDOGENOUS INFLAMMATORY STIMULI AND TOLL-LIKE RECEPTORS

TLRs are a family of pattern-recognition receptors (PRRs) in mammals that can distinguish between chemically diverse classes of genetically conserved microbial products (Table 3-10). These receptors play a central role in the release of inflammatory cytokines from the innate immune system in response to microbial structures, such as exogenous microbial substances and endogenous products. In addition, TLRs likely play a role in the adaptive immune response, which develops during the acute inflammatory response.

Exogenous microbial products, often with redundant molecular structure, are termed pathogen associated molecular patterns (PAMPs) and include substances such as LPS, peptidoglycan, and lipoteichoic acid. PAMPs can bind several types of receptors (PRRs). These receptors include secreted receptors that circulate in the blood (LPS binding protein), surface receptors (macrophage mannose receptors), nucleotide-binding oligomerization domain (NOD) receptors, and surface receptors (TLRs) of the TLR family (Fig. 3-17, Table 3-10). These receptors have different mechanisms by which they activate the cell and some work together. LPS, for example, is bound by LPS binding protein which, in turn, binds CD14 and TLR4. The formation of a PRR-PAMP complex initiates transmembrane signaling that often involves a MyD88 protein event leading to NF kappa B activation and MAPK (p38) signaling. The NF kappa B family of transcription factors initiates gene transcription and translation, resulting in the expression of proteins involved in many cellular processes such as cell proliferation, differentiation, apoptosis, and cell responses to injury, stress, and external pathogens (Fig. 3-18). NF kappa B and p38 then can induce phagocytosis by leukocytes, dendritic cell activation, release of inflammatory cytokines and chemokines, and the activation of the innate (defensin and antimicrobial peptide release) and adaptive (T<sub>H</sub>1 and T<sub>H</sub>2 activity) immune systems. On some occasions, TLR4 signaling does not engage MyD88 (MyD88-independent signaling) and results in the formation of interferon- $\beta$  (IFN- $\beta$ ) and IFN-inducible gene products. Intracellular receptors, such as the NOD receptors, bind peptidoglycan. NOD1

134

135

## Pathologic Basis of Veterinary Disease, 4th Edition

binds to peptidoglycan-derived tripeptide structures, whereas NOD2 binds peptidoglycan-derived muramyl dipeptides. Bound NOD 1 and 2 activate the protein kinase RICK, which then induces NF kappa B activity and eventual secretion of proinflammatory cytokines, such as IL-1 and TNF.

**Table 3-10 Types of Pathogen Associated Molecular Pattern (PAMP) Exogenous Ligands, Their Pattern Recognition Receptors (PRRs), and the Subsequent Action Related to Acute Inflammation**

<b>Exogenous PAMP Ligands</b>	<b>Secreted PRRs</b>	<b>Action</b>
Mannose	Mannan-binding lectin (MBP)	Complement activation
Microbial membranes	C-reactive protein (CRP) and serum amyloid protein (SAP)	Opsin, complement activation
Lipopolysaccharide (LPS)	LPS-binding protein (LBP)	LPS binding
	<b>Cell Surface PRRs</b>	
LPS, peptidoglycan	CD14	Co-receptor for TLR
Mannose	Macrophage mannose receptor	Phagocytosis
Bacterial cell walls	MARCO	Phagocytosis
	<b>Intracellular PRRs</b>	
dsRNA	dsRNA activated protein kinase	NF kappa B and MAPK signaling
Peptidoglycans	Nucleotide-binding oligomerization domain (NOD)	NF kappa B and MAPK signaling
Numerous ligands ( <a href="#">Table 3-12</a> )	Toll-like receptors (TLR)	NF kappa B and MAPK signaling
<b>Endogenous PAMP ligands</b>	<b>Endogenous PRPs</b>	<b>Action</b>
Heparan sulfate, hyaluronic acid, heat shock protein 60 and 70, endoplasmic reticulum glycoprotein 96, fibronectin, fibrinogen, surfactant protein A	Growth factor receptors, CD44, Toll-like receptors, TGF- $\beta$ R, gp IIb/IIIa, surfactant protein receptor 210 (myosin XVIIIa)	Numerous cellular responses including cellular activation, proliferation, and/or apoptosis
Data from Medzhitov R: <i>Nat Rev Immunol</i> 1:135–142, 2001. Endogenous inflammatory stimuli are those produced by host cells.		
<i>gp</i> , Glycoprotein; <i>MAPK</i> , mitogen-activated protein kinase; <i>MARCO</i> , class A scavenger receptor macrophage receptor with collagenous structure; <i>NF</i> , nuclear factor; <i>TGF-<math>\beta</math>R</i> , transforming growth factor- $\beta$ receptor.		

**Fig. 3-17 Pathogen associated molecular patterns (PAMPs).** PAMPs such as lipopolysaccharide (LPS), teichoic acid, and CpG, as well as other endogenous substances, have affinities to certain Toll-like receptors (TLRs) and result in activation of TLR signaling as well as inflammatory and other responses. Endogenous molecules can also activate TLRs and include: heparan sulfate, hyaluronan, heat shock protein 60 (mitochondria), heat shock protein 70 (cytoplasm), fibronectin, fibrinogen, and surfactant protein A. Ligands for TLR10 are not known; TLR11 ligands include uropathogenic bacteria. CD14, LPS binding protein receptor; CpG, bacterial cytosine-phosphate-guanine motifs; GPI, glycosylphosphatidylinositol; MD-2, accessory extracellular adaptor protein that binds TLR4; RSV, respiratory syncytial virus. (Modified from Medzhitov R: Nat Rev Immunol 1:135-142, 2001.)

Endogenous molecules (not produced by microbes) such as exudate sulfate, hyaluronan, HSP 60 (mitochondria), HSP 70 (cytoplasm), Gp 96 (endoplasmic reticulum), fibronectin, fibrinogen, and surfactant protein A can also bind PRRs such as TLR4 and initiate cell signaling, inflammation, and activation of the innate immune system (Table 3-10). These molecules are often overlooked when considering acute inflammation in the context of microbial infections, because microbial products, such as teichoic acid and LPS

## Pathologic Basis of Veterinary Disease, 4th Edition

---

are very potent activators of acute inflammation. However, endogenous molecules likely have a significant role in inflammation generated against neoplastic cells, toxins, and mechanical injury.

### 3.9.10 ANTIMICROBIAL PEPTIDES AND COLLECTINS

Antimicrobial peptides, such as the  $\alpha$ - and  $\beta$ -defensins, cathelicidins, and others—such as anionic peptides, histatins, and dermacidins—are small peptides with microbicidal activity against gram-negative and gram-positive bacteria, fungi, mycobacteria, and some enveloped viruses such as human immunodeficiency virus (HIV) (Table 3-11). They are encoded by genes of the cells involved in the inflammatory response, especially neutrophils, and by epithelial cells forming the skin and the mucosal barriers of the respiratory and alimentary systems. The microbicidal activity likely occurs through the formation of pores within bacterial membranes and viral envelopes. In addition to the microbicidal activity, antimicrobial peptides are increasingly becoming appreciated for their role in other nonmicrobial activities related to inflammation and wound repair. These activities include chemotaxis of leukocytes and dendritic cells, cell proliferation, wound repair, cytokine release, and the protease-antiprotease balance. There is also much evidence that antimicrobial peptides link the innate and adaptive immune responses.

**Fig. 3-18 Toll-like receptor 4 (TLR4).** TLR4, when bound by certain microbial or endogenous products, initiates signaling that leads to release of inflammatory cytokines, such as interleukin (*IL-1*) and tumor necrosis factor (*TNF*), antimicrobial peptides, and molecules that initiate adaptive immunity. Ligand: Lipopolysaccharide (*LPS*). Selected signaling molecules: Toll/IL-1 receptor (TIR) cytoplasmic domain, cytoplasmic protein adaptors to TIR (*TIRAP*, *MyD88*, *TRAF*), IL-1 receptor–associated kinases (*IRAK*), dsRNA-responsive protein kinase (*PKR*), TNF receptor–associated factor 6 (*TRAF 6*), protein kinase (*TAK 1*), map-kinase kinase (*MKK*), interferon regulatory factor 3 (*IRF 3*). Transcription factors: Nuclear factor kappa B (*NF kappa B*), c-Jun N-terminal kinase (*JNK*), p38. *MD-2*, accessory protein; *TRAM*, TRIF-related adaptor molecule; *TRIF*, TIR-containing adaptor inducing interferon- $\beta$ . (Modified from Medzhitov R: *Nat Rev Immunol* 1:135, 2001.)

There are a wide variety of antimicrobial peptides; however, the defensins have received the most attention for activities other than microbial killing. There are three types of defensins: the  $\alpha$ -,  $\beta$ - and  $\tau$ -defensins.  $\alpha$ -Defensins are produced by neutrophils and Paneth cells.  $\beta$ -Defensins are produced by neutrophils and epithelial cells.  $\tau$ -Defensins are produced in neutrophils of primates. The defensins are cationic proteins with three pairs of intramolecular disulfide bonds.  $\alpha$ -Defensins and  $\beta$ -defensins can stimulate mast cell degranulation, induce IL-8 synthesis, induce T lymphocyte chemotaxis, and activate T lymphocytes, macrophages, and dendritic cells, thus interconnecting innate and adaptive immunity. The importance of defensins in immunity is underscored by the fact that HIV-1 infected individuals that are healthy and in “remission” have high concentrations of  $\alpha$ -defensins, which are thought to enhance T-lymphocyte activity and may also have direct anti-HIV-1 activity.

**Table 3-11 Inflammatory and Other Activities of Antimicrobial Peptides and Surfactant Proteins**

Antimicrobial Peptide/Protein	Major Cell of Production	Activity
$\alpha$ -Defensins	Enterocytes, leukocytes	Microbicidal activity, induce interleukin-8 production (cryptidins), inhibit angiogenesis (neutrophil $\alpha$ -defensins)
$\beta$ -Defensins	Epithelia, leukocytes	Microbicidal activity, chemotactic for neutrophils, dendritic cells, other leukocytes, induce cell proliferation
Cathelicidins	Leukocytes, epithelia	Microbicidal activity, induce cytokine and histamine release, regulate cell proliferation, angiogenesis, wound healing, prevent apoptosis (PR-39)
Surfactant proteins A and D	Epithelia	Opsonization of pathogens, macrophage activation
Cryptidins = a type of $\alpha$ -defensin produced by Paneth cells; neutrophil $\alpha$ -defensins = $\alpha$ -defensins produced by human neutrophils; PR-39 = a cathelicidin molecule produced by porcine neutrophils.		

Collectins are molecules with a collagen-like domain and lectin binding-portion that also activate and regulate inflammatory responses. Surfactant proteins (SPs) are collectins that mediate inflammatory responses in the lung, other areas of the respiratory tract mucosa, and other organs such as the ear canal. There are four surfactant proteins (A, B, C, and D) involved with surfactant production, processing, and regulation in the lung. Two of these, A and D, also regulate inflammatory responses. SP-AD can opsonize and aggregate viral and bacterial pathogens and also activate macrophages, induce uptake of apoptotic cells, and increase or decrease production of TNF and reactive oxygen species in response to infectious agents. SP-AD bind several different receptors that include SIRP (signal inhibitory regulatory protein) and SHP1 (SRC homology SH2 domain containing protein tyrosine phosphatase 1); SP-R210 (surfactant protein receptor 210); TLR2; TLR4; CD91; AND C1qr (complement 1 receptor). Once triggered, these receptors alter NF kappa B activity and inflammatory cell activation. Mannose-binding protein is a collectin produced by hepatocytes (acute phase protein) and is present in the serum. Mannose-binding protein can opsonize pathogens and activate complement. Impaired expression of SP-A, SP-D, and mannose-binding protein is associated with increased susceptibility to infection.

## 3.9.11 ACUTE PHASE PROTEINS

Acute phase proteins are plasma proteins synthesized in the liver whose concentrations increase (or decrease) by 25% or more during inflammation. These proteins serve as inhibitors or mediators of the inflammatory processes and include C-reactive protein,  $\alpha_1$ -acid glycoprotein, haptoglobin, mannose-binding protein, fibrinogen,  $\alpha_1$ -antitrypsin, and complement components C3 and C4. The concentration of these acute phase proteins usually increases during inflammation, whereas the concentration of prealbumin and albumin (also

## Pathologic Basis of Veterinary Disease, 4th Edition

acute phase proteins) decreases in inflammation. Acute inflammatory conditions that are severe enough to raise blood plasma concentrations of cytokines, such as IL-1 and TNF, increase the blood concentrations of acute phase proteins. C-reactive protein has recently received attention as a marker of inflammatory conditions, especially atherosclerosis in human beings. In addition to its role diagnostically, C-reactive protein binds to bacteria and fungi and also activates complement. Once acute phase proteins and systemic levels of inflammatory cytokines are elevated, they affect the heart rate, blood pressure, and the hypothalamic regulation of temperature by directly or indirectly stimulating neurons within specific hypothalamic nuclei. The previously described changes also affect respiratory rates and gaseous exchange.

### 3.9.12 SUMMARY OF THE CHEMICAL MEDIATORS OF ACUTE INFLAMMATION

Various exogenous and endogenous stimuli can activate TLRs, Fc receptors for IgE, or simply cause mechanical or other damage to invoke an acute inflammatory response (Table 3-3). This response can occur very rapidly as the result of the release of preformed or rapidly activated inflammatory mediators such as histamine, kinins, complement factors like C3a and C5a, and tachykinins (substance P). These molecules generally affect vascular caliber and permeability and activate leukocytes and endothelial cells. Concurrently, lipid-based products such as prostaglandins, leukotrienes, and PAF contribute to chemotaxis, vascular tone, and leukocyte activity, all of which work in concert with chemokines and cytokines to activate endothelial cells and leukocytes and enhance neutrophil infiltration. Nitric oxide released by macrophages and endothelia induce vasodilation and also contribute to tissue damage caused by other reactive oxygen species. Inflammatory mediators bind receptors that subsequently induce cytoplasmic signaling and cellular activation, resulting in the production of additional cytokines, adhesion molecules, and other inflammatory mediators that may either exacerbate or inhibit the inflammatory process. Activated neutrophils expressing leukocyte adhesion molecules, such as the integrins, enter inflamed tissue and can release hydrolytic enzymes and other granule contents that further damage tissue. Systemically, increases in acute phase proteins and cytokines can affect body temperature, cardiovascular function, locomotion, sleep, appetite, and other activities.

As the previously described process has been studied over the years, therapeutic intervention to regulate the inflammatory process has become more precise. Early on, some home remedies, such as the use of the bark of the willow tree (*Salix* sp.) by Greeks, Chinese, Europeans, and Native Americans to alleviate pain, seemed far from scientific until it was discovered that the bark of these trees contained salicin, a component of acetylsalicylic acid (aspirin). Now, drugs that inhibit receptors, receptor signaling, and gene expression can prevent very specific pathways of the inflammatory process. It is up to the veterinary clinician to remain current in her or his knowledge of the steps of the inflammatory response to gain optimal benefit from newly developed therapies.

### 3.10 INFLAMMATION AND THE SENSATION OF PAIN

Several features of inflammatory response activate sensory nerve fibers. Mechanoreceptors can sense changes in tissue swelling secondary to the accumulation of edema fluid and/or exudates. Thermoreceptors can sense changes in localized or systemic temperatures. Pain receptors can also become activated. Concerning pain, release of prostaglandin E<sub>2</sub> is a crucial mediator of the inflammatory pain sensation. PGE<sub>2</sub> mediates this activity through a specific glycine receptor subtype (GlyR  $\alpha$ -3) of the dorsal gray horn of the spinal cord. Inhibition of PGE<sub>2</sub> expression through inhibition of COX enzymes reduces pain and future therapies may target GlyR  $\alpha$ -3 receptors.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 3.11 THE EFFECT OF INFLAMMATION ON THE FEBRILE RESPONSE AND OTHER ACTIVITIES

Cytokines such as IL-1, TNF, and IL-6, as well as high mobility group protein box-1 (HMGB-1) molecules are often produced during acute inflammatory responses. These inflammatory mediators, along with LPS (microbial factor) and other potentially toxic microbial or chemical molecules, are important regulators of body temperature (fever), malaise, headache, confusion, anorexia, locomotion, and unconsciousness. Many of these actions occur through: (1) the effects of these cytokines on sensory fibers in the vagus nerve, which extends to the brain stem, and (2) their effects on cerebral endothelial cells, perivascular microglia, and meningeal macrophages and the ability of the cells to induce COX-1, COX-2, and COX-3 activity for the formation and release of prostaglandins such as PGE<sub>2</sub>. PGE<sub>2</sub> then activates various hypothalamic nuclei, including the ventromedial preoptic nucleus, paraventricular nucleus, solitary tract nucleus, ventrolateral medulla, and parabrachial nucleus, which regulate fever and the other clinical responses listed previously.

### 3.12 UNIQUE TYPES OF INFLAMMATION

#### 3.12.1 SEPTICEMIA AND ENDOTOXIC SHOCK

##### 3.12.1.1 SEPTICEMIA

Septicemia is a clinically significant form of bacteremia complicated by toxemia, fever, malaise, and often shock (Table 3-12). Septicemia is characterized by the multiplication of microorganisms within the bloodstream and “seeding” into blood from fixed microcolonies present in one or more tissues. In septicemia, inflammation is not a well-controlled local reaction to injury, but instead mediators of inflammation are generated systemically leading to diffuse “leakage” of plasma into the interstitium and sequestration of leukocytes in the microvasculature. Generation of cytokines, kinins, vasoactive amines, and lipid mediators of inflammation, combined with widespread endothelial damage, leads to profound circulatory disturbances. Because of the systemic nature of this host-microbial interaction, quantities of phagocytic cells, antibody, complement components, and coagulation proteins may become depleted unless septicemia is controlled in the early stages. Septic shock and disseminated intravascular coagulation (DIC) are the usual sequelae of advanced bacterial septicemia.

138

139

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 3-12 Examples of Differing Types of Inflammatory and Clinical Responses to Stimuli

	TYPE OF INFLAMMATORY STIMULI		
	Skin Allergen	Gram-Negative Bacterial Infection in Dermis	Gram-Negative Septicemia
<b>Stimulus</b>	Allergen	LPS, toxins	LPS, toxins
<b>Site</b>	Epidermis/dermis	Dermis	Blood
<b>Molecular trigger</b>	Immunoglobulin E–cross-linking, dendritic cell binding	TLR4, CD14	Hageman factor, complement, TLR4
<b>Major response</b>	Histamine, leukotrienes	IL-1, TNF, prostaglandins, PAF, neutrophil products	Kinins, bradykinin, PAF, prostaglandins, IL-1, TNF
<b>Extent of response</b>	Local	Local	Systemic
<b>Clinical finding</b>	Swelling, pruritus (bronchoconstriction)	Swelling, exudate (pus)	Fever, nausea, malaise
<b>Desired resolution</b>	Limited, resolves in hours/days	Limited, resolves in days	Transient, resolves
<b>Possible sequelae</b>	Severe wheal and flare, anaphylaxis	Cellulitis leading to ulceration, eventual fibrosis/granuloma	Septic shock
CD14 = receptor for LPS-binding protein. Hageman factor = clotting factor.			
IL-1, Interleukin-1; LPS, lipopolysaccharide (endotoxin); PAF, platelet-activating factor; TLR4, Toll-like receptor 4; TNF, tumor necrosis factor.			

Septicemia should be differentiated from a bacterial embolism. For example, some strains of *Streptococcus* spp. may break free from vegetative lesions (valvular endocarditis), as large colonies are protected by cell debris and fibrin. The bacterial emboli may then mechanically lodge in the lung, liver, kidney, or brain to produce a secondary focus of infection (abscess), but the whole process remains subclinical. In such a case, the blood sample taken for culture often lacks viable bacteria.

### 3.12.1.2 ENDOTOXIC SHOCK

The systemic interaction of microorganisms and their products (toxins) with a spectrum of host cells and chemical mediators results in a clinical syndrome recognized as sepsis or septic shock (Table 3-12). The host mediators and amplification systems initiating the syndrome vary with the type of organism and the nature of the infectious process (local or systemic). Regardless of the specific cause, the major elements of septic shock form a continuum including: (1) hemodynamic derangements, (2) abnormal body temperature, (3) progressive hypoperfusion of the microvasculature, (4) hypoxic injury to susceptible cells, (5) quantitative adjustments in blood leukocytes and platelets, (6) DIC, (7) multiple organ failure, and (8) death.

Bacterial endotoxin, the LPS from the outer membrane of gram-negative bacteria, has been studied extensively as an initiator of septic shock. The peptidoglycan layer of gram-positive bacteria and bacterial exotoxins can initiate many of the same host responses. Other important initiators are products of the interaction of neutrophils, macrophages, and platelets with microorganisms in the tissue. Endotoxin is bound in the serum by lipopolysaccharide binding protein (LPB) that binds CD14. Endotoxin has numerous ways to induce systemic activation of inflammatory mediators. Three direct effects of endotoxin are the activation of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Hageman factor (a clotting factor), the complement cascade, and induction of the TLR4 pathway. These pathways can ultimately activate bradykinin, PAF, arachidonic acid metabolites, and cytokines (IL-1 and TNF), all of which have a role in many of the coagulation, hemodynamic, thermoregulatory, and leukocyte derangements observed in septic shock. TNF is capable of producing most clinical and pathologic features of septic shock, including: hypotension, metabolic acidosis, hemoconcentration, intestinal hemorrhage, fever, neutrophil and endothelial activation, and predisposition to thrombosis. IL-1 shares many of the biologic activities of TNF in the mediation of septic shock. Secretion of TNF by activated macrophages can be partially inhibited by pretreatment with glucocorticoids such as dexamethasone, which have been used therapeutically, often with limited success. In addition, lethal shock is prevented with anti-TNF antibody or TNF receptor inhibitors.

In severe septicemia, a systemic inflammatory response syndrome (SIRS) can develop in which there is extensive accumulation of cytokines, activated neutrophils, and platelets in the circulatory system. This result leads to multiple organ failure (MOF) and shock. Most patients survive initial SIRS insults, but these individuals are at increased risk of secondary or opportunistic infections termed compensatory antiinflammatory response syndrome (CARS). The initial activation of innate immunity can lead to decreased macrophage activity, T-cell anergy, and apoptosis of lymphocytes contributing to CARS.

139

140

Multiple organ failure (MOF) represents a late stage in septic shock and accounts for much of the irreversibility of organ failure. Systemic tissue ischemia and hypoxia, associated with progressive cardiovascular derangements, increased vascular leakage, and DIC, lead to generalized organ failure. Organs that are particularly sensitive to these effects include: heart, brain, kidney, lung, liver, and intestinal mucosa. Cells injured by ischemia revert to anaerobic energy production (glycolysis), resulting in rapid depletion of substrates (glycogen, glucose), accumulation of lactate, and a deficiency of ATP. Without sufficient ATP, cell membrane ion pumps fail to maintain electrolyte balances, membrane integrity, and protein synthesis. The influx of sodium into cells with water causes cells to swell with further loss of function. Influx of calcium ions activates many intracellular enzymes, including phospholipase, which breaks down cellular membranes and generates arachidonic acid products. Loss of the proton gradient of the inner mitochondrial membrane makes oxidative phosphorylation impossible. Irreversible cell injury is believed to be closely related to generalized failure of mitochondria and loss of selective permeability of cell membranes.

Animals dying of septic shock typically have evidence of fluid in the body cavities, pulmonary edema, petechial hemorrhages, congestion of the liver and intestines, and dehydration. Common microscopic lesions include acute necrosis of renal tubules, centrilobular hepatocytes, cardiac myocytes, adrenals, and tips of intestinal villi.

### 3.13 MORPHOLOGIC CLASSIFICATION OF EXUDATES IN ACUTE INFLAMMATORY LESIONS

The gross and microscopic appearance of different types of acute inflammatory reactions in tissue can often be classified according to the vascular and cellular components of the response, thus providing a mechanistic basis for understanding the pathogenesis. Histopathologic lesions of acute inflammation are most commonly grouped into five categories: serous, catarrhal, fibrinous, suppurative or purulent, and hemorrhagic, or a combination of these lesions, such as fibrinosuppurative. Similar histopathologic patterns of lesions also occur in chronic inflammation (lymphomonocytic/lymphohistiocytic or granulomatous [macrophages, multinucleate giant cells, lymphocytes, plasma cells, fibrosis]) and will be discussed in [Chapter 4](#).

It should be recognized that the histopathologic lesions of acute inflammation often represent: (1) a continuum of progressive changes of the same type of inflammation occurring over time or (2) different types of inflammatory responses occurring concurrently in the same or different areas of an affected tissue. Therefore as an example,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

rhinitis could progress in a sequence from serous to catarrhal to mucopurulent to purulent. If the inciting stimulus is severe, changes could progress rapidly from serous to fibrinous to hemorrhagic.

### 3.13.1 SEROUS INFLAMMATION

Serous inflammation is the term used to describe a pattern of acute inflammation in which the tissue response consists of the leakage or accumulation of fluid with a low concentration of plasma protein and no to low numbers of leukocytes. This watery material is released from small gaps between endothelial cells and from hypersecretion of inflamed serous glands. This response is essentially a transudate (specific gravity <1.012) and is seen with: (1) thermal injury to skin, such as burns and photosensitization, in which the lesion can appear as a fluid-filled blisters or (2) acute allergic responses characterized by watery eyes and a runny nose with a clear, colorless transudate.

Grossly, lesions, for example, with serous inflammation consist of tissue that: (1) contains excessive clear to slightly yellow, watery fluid that leaks from the tissue on cut section or (2) forms raised fluid-filled vesicles protruding above the surface of the mucous membrane of the nasal cavity (serous rhinitis) or of the skin (Fig. 3-19). Microscopically, connective tissue fibers are separated, often widely, and capillaries and postcapillary venules are dilated with erythrocytes (active hyperemia). Endothelial cells lining these vessels can vary from flattened to hypertrophied.

### 3.13.2 CATARRHAL INFLAMMATION

Catarrhal inflammation or mucoid inflammation is the term used to describe a pattern of acute inflammation in which the tissue response consists of the secretion or accumulation of a thick gelatinous fluid containing abundant mucus and mucins from a mucous membrane. This response occurs most commonly in tissue with abundant goblet cells and mucus glands, such as in certain types of chronic allergic and autoimmune gastrointestinal diseases and with chronic inflammation of the airways of the respiratory system (chronic asthma). Grossly the surface or cut surface of affected tissue may be covered with or contain, a clear to slightly opaque, thick fluid (Fig. 3-20). Microscopically the lesion can include hyperplastic epithelial cells of mucus

glands and goblet cells, as well as connective tissue fibers separated by mucins.

140

141

**Fig. 3-19 Serous exudate/subcutaneous edema, photosensitization, skin of the nose and ears, ewe.** **A**, The nonhaired skin of the nose is covered by a crust resulting from dehydration of the serous exudate released from injured blood vessels following a short exposure to the sun. The ears are edematous and droopy. **B**, Microscopically, there is moderate expansion of the superficial dermis with edema secondary to vascular leakage (serous inflammation). The postcapillary venules are dilated (active hyperemia), and leukocytes can be observed marginating on endothelia. H&E stain. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 3-20 Catarrhal inflammation.** **A**, Abomasum, cow. The mucosal epithelium is moderately thickened, covered by a glistening layer of clear mucus, and has a subtle nodular appearance caused by accumulation of mucinous secretory products (catarrhal exudate) in the gastric pits. **B**, Colon, cow. Microscopically, there is a catarrhal colitis with hyperplasia of mucosal epithelial cells and increased accumulation of mucus on the mucosal surface. H&E stain. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

### 3.13.3 FIBRINOUS INFLAMMATION

Fibrinous inflammation is the term used to describe a pattern of acute inflammation in which the tissue response consists of the accumulation of fluid with a high concentration of plasma protein (specific gravity >1.02) and no to low numbers of leukocytes. This response is an exudate. Fibrinous inflammation occurs with more severe endothelial cell injury that allows leakage of large molecular weight proteins, such as fibrinogen. Fibrinogen leaks from capillaries and postcapillary venules during the fluidic phase of the acute inflammatory response and polymerizes outside of the vessels to fibrin, a homogenous and vividly pink (eosinophilic) protein when stained with hematoxylin and eosin (H&E). This lesion is most commonly caused by infectious microbes and is seen in the serous membranes of the body cavities, such as those lined by pleura (fibrinous pleuritis), pericardium (fibrinous pericarditis), peritoneum (fibrinous peritonitis), and in the synovial membranes of joints (fibrinous synovitis or polyserositis) and the meninges (fibrinous leptomeningitis). Common examples include the lesions in pulmonary alveoli in fibrinous pneumonia (*Mannheimia haemolytica*), atypical interstitial pneumonia (3-methylindol), and respiratory viral infections (infectious bovine rhinotracheitis [IBR] in cows). When fibrin forms a distinct layer covering an ulcer, it is referred to as a fibrinous pseudomembrane, whereas when it lines the pneumonocyte surface of lung alveoli and is mixed with necrotic cell debris such as occurs with bovine respiratory syncytial virus (BRSV) infection, it is called a hyaline membrane.

141

142

Grossly the surfaces of affected tissue are red (active hyperemia) and covered with a thick, stringy, elastic, white-gray to yellow exudate that can be removed from the surface of the tissue (in contrast to a fibrous response) (Fig. 3-21). A classic example of fibrinous inflammation occurs in fibrinous pneumonia caused by acute *Mannheimia haemolytica* infection, where both alveoli and stromal connective tissue (interlobular septa) contain notable fibrinous exudate that rapidly becomes infiltrated by neutrophils, resulting in a fibrinosuppurative exudate. Another example of fibrinous inflammation occurs in IBR, caused by a herpesvirus that injures epithelial cells of the respiratory tract, resulting in an acute fibrinous inflammatory response. Noninfectious causes, such as heat and smoke inhalation, can cause fibrinous exudate in the trachea. Microscopically, capillaries and postcapillary venules are dilated with erythrocytes (active hyperemia), and endothelial cells are reactive (hypertrophied). The stromal connective tissue or the mesothelial surfaces of the affected organ contains or is covered by red to vividly red layers of coagulated and/or polymerized fibrin, albumin, and other plasma proteins. The fibrinous exudate is often rapidly infiltrated by neutrophils resulting in fibrinosuppurative inflammation.

**Fig. 3-21 Fibrinous inflammation, pleural cavity, visceral and parietal pleurae, horse.** **A**, The pleural surfaces are covered by a yellow-gray, thick, friable exudate consisting of fibrin mixed with other plasma proteins. This exudate can be easily pulled apart and should not be confused with fibrous adhesions. The latter response occurs over time and consists of a similar appearing material that contains collagen fibers. These fibers provide tensile strength to the material and form adhesions between opposing surfaces that can only be broken with some difficulty. **B**, Microscopically, there are layers of homogenous red material (fibrin-fibrinous exudate) that contain occasional neutrophils and a focus of bacteria (arrows). H&E stain. (**A and B**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

### 3.13.4 SUPPURATIVE INFLAMMATION

Suppurative inflammation is the term used to describe a pattern of acute inflammation in which the tissue response consists of the accumulation of fluid with a high concentration of plasma protein (specific gravity  $>1.02$ ) and high numbers of leukocytes, predominately neutrophils. This material is an exudate commonly known as pus. Pus can be a creamy liquid, but if dehydrated it can be more caseous and firm in consistency and occasionally laminated in diseases such as ovine caseous lymphadenitis. A circumscribed collection of pus visible grossly is called an abscess, whereas, if visible only microscopically, it is called a microabscess.

**Fig. 3-22 Suppurative (purulent) inflammation, secondary bacterial bronchopneumonia, infectious canine distemper, puppy.** **A**, The cranioventral areas of the lung are firm and beige to brown. This lesion is caused by neutrophils transmigrating into alveoli in an acute inflammatory response secondary to bacterial infection of the lung. **B**, Microscopically, alveoli contain numerous neutrophils (suppurative exudate) and sloughed pneumocytes. H&E stain. (*A and B, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

142

Dense neutrophil accumulation (pus) can also be distributed in tissue layers such as fascial planes and subcutaneous connective tissue and is referred to as cellulitis or phlegmonous inflammation. Instead of producing a focal abscess, the neutrophils evoke a watery suppurative exudate distributed along fascial planes and tissue spaces, as in some cases of blackleg or extensive gram-positive (staphylococcal) infection. Suppurative inflammation, microabscesses, abscesses, and exudates are most commonly caused by bacteria, including *Staphylococcus* spp., *Streptococcus* spp., and *Escherichia coli*, and can occur in many organs. These genera can also cause suppurative bacterial meningitides in the CNS. Abscesses in the brains of horses caused by *Streptococcus equi* and microabscesses in the brains of cows caused by *Listeria monocytogenes* are good examples of suppurative inflammation. Bacteria-induced suppurative inflammation also occurs commonly in: (1) the pelvis and tubules (pyelonephritis) of the kidney, (2) the bronchi of the lungs (bronchopneumonia), (3) the nasal and sinus cavities (rhinitis and sinusitis), (4) the glandular epithelium of the prostate (prostatitis), (5) the lumina of the gall bladder (cholecystitis) and urinary bladder (urocystitis), and (6) the acini and ducts of the mammary gland (mastitis). Unresolved suppurative inflammation can progress to chronic inflammation.

143

Grossly the surfaces and/or connective tissues of affected organs are hyperemic and covered by or contain, respectively, a thick white-gray to yellow pus (Fig. 3-22). In some cases, pus will be mixed with fibrin, forming a fibrinosuppurative exudate. Microscopically, affected tissues have large numbers of neutrophils; many degenerate and often are mixed with necrotic cellular debris, bacteria, plasma proteins, and fibrin.

### 3.14 NOMENCLATURE OF THE INFLAMMATORY RESPONSE (MORPHOLOGIC DIAGNOSES)

Nomenclature, a system of names assigned to structures and processes in a scientific discipline, used in veterinary pathology provides clinicians with a morphologic diagnosis, a precise description of the process, type of inflammation, and disease. A morphologic diagnosis has six components listed in the following sequence: degree

## Pathologic Basis of Veterinary Disease, 4th Edition

of severity, duration, distribution, exudate, modifier, and tissue (Table 3-13). Based the results of a postmortem examination and/or histologic evaluation of tissue specimens, a pathologist will construct a morphologic diagnosis by including, in sequential order, the components of the nomenclature that best describe the specimens. For example, using the kidney as the injured tissue, the central component of a morphologic diagnosis is the name of the tissue derived from its Latin term, “nephro-.” If the kidney is inflamed, the prefix “nephro-” is combined with the suffix “itis” (inflammation or disease of) to form the word “nephritis,” meaning inflammation of the kidney. The other components of the morphologic diagnosis, such as degree, duration, distribution, exudate, and modifier, precede nephritis and are used to describe the characteristics of the inflammatory process. The pattern of distribution of the inflammatory lesion not only provides location but in many instances implies a mechanism of injury. These patterns of distribution are shown in Fig. 3-23 and include focal, multifocal, locally extensive, and diffuse. They will be covered in greater detail in each organ system. The subtleties of this process are learned through advanced training in the discipline of pathology, and terms describing the degree and duration evolve from professional experience and are not likely to be mastered by veterinary students during their professional training.

143

144

**Table 3-13 The Nomenclature of a Morphologic Diagnosis**

Degree	Duration	Distribution	Exudate	Modifier	Tissue
Minimal	Acute	Focal	Serous	Necrotizing	Nephritis
	Subacute	Multifocal	Catarrhal	Bronchointerstitial	Cystitis
Mild	Chronic	Locally extensive	Fibrinous	Hemorrhagic	Enteritis
Moderate	Chronic-active	Diffuse (interstitial)	Suppurative	Embolic	Pneumonia
Marked (severe)		Cranioventral <sup>†</sup>	Granulomatous		Hepatitis

This table provides an example of how nomenclature can be used to construct a morphologic diagnosis. It is not intended to be all inclusive and may vary from schemes used in other veterinary colleges.

\* In the lung, it is customary to use the term *pneumonia* to indicate inflammation of the lung.

† Used only for diseases of the lungs.

**Fig. 3-23 Patterns of lesion distribution used to construct morphologic diagnosis, as an example, in the kidney. (From Slauson DO, Cooper BJ: Mechanisms of disease: a textbook of comparative general pathology, ed 3, St Louis, 2002, Mosby.)**

## Pathologic Basis of Veterinary Disease, 4th Edition

For completeness in this discussion, morphologic diagnoses can also use the suffixes “osis” (diseased or abnormal condition) or “opathy” (disease). In this context, such diseases or conditions refer to those caused by degenerative or aging processes without inflammation. Therefore the same nomenclature can be used to diagnose a degenerative condition in the kidney by using the term “nephrosis or nephropathy.” The other components are then added to nephrosis or nephropathy to describe the characteristics of the degenerative process. Finally, some metabolic and neoplastic diseases do not fit into this nomenclature, but equally valid morphologic diagnoses can be constructed. An enlarged, soft and friable, yellow, and greasy liver can be morphologically diagnosed as “fatty liver” (hepatic lipidosis), whereas a solid, firm, white expansile mass in the liver could be morphologically diagnosed as “hepatic malignant lymphoma.”

## 3.16 APPENDIX 3-1 Mediators of Inflammation

146

Mediator	Source	Structure	Stimulus	A <sup>+</sup> B <sup>+</sup> C <sup>+</sup>	Activity	Receptor/Signaling	Inhibitors
<b>VASOACTIVE AMINES</b>							
Histamine	Mast cells, basophils, platelets	Decarboxylated histidine	Trauma, cold, cross-linking of IgE, C3a, C5a	+	++ +/- Endothelial cell retraction, smooth muscle cell contraction	Histamine binds H <sub>1</sub> and H <sub>2</sub> receptors	H <sub>1</sub> and H <sub>2</sub> inhibitors, enzymatic degradation
Serotonin	Rodent mast cells and basophils	5-hydroxy-tryptamine	Trauma, cold, cross-linking of IgE, C3a, C5a	+	++ +/- Endothelial cell retraction, smooth muscle contraction		
<b>TACHYKININS</b>							
Substance P	Nerve fibers, macrophages		Neuronal activation, histamine	+	++ + Endothelial cell retraction, smooth muscle contraction, leukocyte activation	Neurokinin receptors	
Neurotachykinin A							
Neurotachykinin B							
<b>PLASMA PROTEASES</b>							
Bradykinin	Plasma proteins	9 amino acid peptide	Negative surfaces, collagen, endotoxin, immune complexes	+	+	- Endothelial cell retraction, smooth muscle cell relaxation, contraction	Plasma and tissue kallikrein with XII, prekallikrein, HMWK, and XI
Lysylbradykinin							Activated by XIIa
Kallikrein	Plasma (Fletcher)	80 kD protein	Contact activation	-	-	+	Cleaves XII, HMWK, activates collagenase
<b>COAGULATION AND FIBRINOLYTIC SYSTEMS</b>							
Clotting cascade and fibrinolysis enzymes	Plasma	60–450 kD proteins	Plasma contact with collagen, basement membranes, endotoxin, immune complexes	-	+/- +/-	Thrombosis and fibrinolysis; activation of kallikrein, bradykinin, complement	Enzymatic cleavage of nonactivate factors results in activity
<b>CELLULAR PROTEASES</b>							
Trypsin/chymase	Mast cells		Histamine, substance P	-	-	-	Cleaves extracellular matrix, activates receptors
<b>COMPLEMENT</b>							
C3a	Plasma proteins	Complement fragments range in size from 75–410 kD	Immune complexes, endotoxin, plasmin, proteases	-	+	+/-	Chemotaxis, leukocyte activation
C5a		Complement fragments range in size of 75–410 kD		-	+	++	Chemotaxis, leukocyte activation
C5, C6, C7		Complement fragments range in size from 75–410 kD		-	-	-	Membrane attach complex that forms pores
C3b		Complement fragments range in size from 75–410 kD		-	-	-	Oponin
<b>EICOSANOIDS PROSTAGLANDINS</b>							
Prostacyclin (PGI <sub>2</sub> )	Endothelial cells	Arachidonic acid metabolite via COX	Cell injury, intracellular calcium release, with PLA <sub>2</sub> activity	+	-	-	Inhibits platelet aggregation on endothelial cells, reduces thrombosis, vasodilation
Thromboxane (TXA <sub>2</sub> )	Platelets	Arachidonic acid metabolite via COX	Platelet activation, with PLA <sub>2</sub> activity	+	-	-	Platelet activation and thrombosis, vasoconstriction
PGE <sub>2</sub>	Variety of cells	Arachidonic acid metabolite via COX		+	+	-	Mediators of sensation to pain, can reduce inflammatory responses, vasodilation
PGF <sub>2</sub>	Endothelial and epithelial cells	Arachidonic acid metabolite via cells		+	-	-	Smooth muscle contraction, vasoconstriction
<b>LEUKOTRIENES</b>							

146

147

# Pathologic Basis of Veterinary Disease, 4th Edition

LTB <sub>4</sub>	Leukocytes	Arachidonic acid metabolite via LOX	Membrane injury, with PLA <sub>2</sub> activity	- +/++	Chemotaxis, leukocyte and endothelial cell activation	G protein-coupled receptor	Aspirin, LOX inhibitors, corticosteroid	
LTC <sub>4</sub> , LTD <sub>4</sub> , LTE <sub>4</sub>	Mast cells, basophils	Arachidonic acid metabolite via LOX	Membrane injury with PLA <sub>2</sub> activity	+ ++ -	Slow-reacting substance of inflammation, vasoconstriction	G protein-coupled receptor	Aspirin, LOX inhibitors, corticosteroid	
PAF	Platelets, endothelial cells, leukocytes	Glycerol-based lipid mediator	PAF	+ ++ ++	Chemotaxis, leukocyte and endothelial cell activation, vasoconstriction	G protein-coupled receptor	PAF acetylhydroxylase	
<b>INTERLEUKINS/CYTOKINES</b>								
IL-1	Macrophages, endothelial cells, leukocytes	17 kD protein	Activated leukocytes and endothelial cells	+ + +	Chemotaxis, leukocyte activation, acute phase protein release, fever, hemodynamics	IL-1 R 1-9, JAK/STAT signaling	IL-1 receptor inhibitors, IL-1 mimetics, COX inhibitors, corticosteroid	
IL-2	T-helper lymphocytes	15 kD protein	Antigenic stimulation, IL-1	- - -	Proliferation of lymphocytes	IL-2 receptor, JAK/STAT signaling	IL-2 receptor inhibitors, IL-1 mimetics, cell-cycle inhibitors	
IL-3	T lymphocytes	20 kD protein	Antigenic stimulation, mitogens	- - -	Growth of bone marrow stem cells, hematopoietic cells, mast cells	CD23	IL-3 receptor inhibitors, mimetics, cell cycle inhibitors	148
IL-4	T <sub>H</sub> 2 lymphocytes	14 kD protein		- - -	T <sub>H</sub> 2 response; NK cell activation	CD124, CD132	IL-4 receptor inhibitors, mimetics	149
IL-5	T <sub>H</sub> 2 lymphocytes	13 kD protein repeated α helix		- - -	T <sub>H</sub> 2 response, eosinophil proliferation	IL-5 R, CD125	IL-5 receptor inhibitors, mimetics	
IL-6	T lymphocytes, macrophages, fibroblast, other cells	26 kD protein	IL-1 and TNF	- - -	Acute phase protein synthesis, antiviral activity, B-lymphocyte differentiation, lung mucus production (with IL-17)	CD126, CD130	IL-6 receptor inhibitors, mimetics	
IL-7	Bone marrow stromal cells	25 kD protein		- - -	B- and T-lymphocyte proliferation in bone marrow	CD127, CD132	IL-7 receptor inhibitors, mimetics	
IL-8	Endothelial cells, leukocytes		Cellular activation	- ++ +	Leukocyte, especially neutrophils, chemotaxis	IL-8 R	IL-8 receptor inhibitors, mimetics, COX inhibitors, corticosteroid	
IL-9				- - -	T <sub>H</sub> 2 response, hematopoiesis	IL-9 R		
IL-10	T regulatory lymphocytes, T <sub>H</sub> 2 lymphocytes, dendritic cells	α Helix		- - -	Decreases dendritic cell activity and T <sub>H</sub> 2 response; in family with IL-19, 20, 22, 24, 26, 28, 29	CRF 2		
IL-11				- - -	Megakaryocyte hematopoiesis	IL-9 R		
IL-12	Dendritic cells and macrophages			- - -	T <sub>H</sub> 1 response, growth, and differentiation of T lymphocytes, NK cell activation	IL-12 R B1, 2		
IL-13				- - -	T <sub>H</sub> 2 response, growth, and differentiation	IL-13 R		
IL-14				- - -				
IL-15	T lymphocytes			- - -	IL-2-like activity (lymphocyte proliferation) and NK cell activation	IL-15 R, CD122		
IL-16	Memory T lymphocytes, mast cells, eosinophils			- - -		CD4		
IL-17	CD4 memory cells			- - +	Chemoattractant for CD4 T-helper lymphocytes	IL-17 R		
IL-18	Macrophages, Kupffer cells			- - -	Synergistic with IL-12 for Th-1 induced activity and IFN-γ release	IL-1 R-related protein		

# Pathologic Basis of Veterinary Disease, 4th Edition

IL-19		$\alpha$ Helix		- - -	In family with IL-10, 20, 22, 24, and 26	CRF 2	
IL-20		$\alpha$ Helix		- - -	In family with IL-10, 19, 22, 24, and 26, implicated in psoriasis	CRF 2	
IL-21	CD4 T lymphocytes			- - -	Induces differentiation of NK cells previously activated by IL-4, IL-12, and IL-15; inhibits recruitment of nonactivated NK cells	IL-2-like R	
IL-22		$\alpha$ Helix		- - -	Induces acute phase protein release; in IL-10 family	CRF 2	
IL-23				- - -	$T_H1$ response similar to IL-12, acts on CD4 lymphocytes		
IL-24		$\alpha$ Helix		- - -	IL-10 family with IL-19, 20, 22, and 26	CRF 2	
IL-25	Mast cells			- - -	$T_H2$ response, induces production of IL-4, 5, and 13		
IL-26		$\alpha$ Helix		- - -	IL-10 family with IL-19, 20, 22, and 24	IL-26 R (IL-20 & IL-10 components)	
IL-27				- - -	$T_H1$ response, stimulates naïve CD4 T lymphocytes; synergistic with IL-12	IL-27 R	
IL-28				- - -	Possibly antiviral like IFN and IL-10	CRF 2	
IL-29				- - -	Similar to IL-28; possibly antiviral	CRF 2	150
IL-31	$T_H2$ lymphocytes		Macrophage activation, epithelial cells		Induces dermatitis in mice	Gp130-like receptor	Receptor inhibitors, JAK/STAT inhibitors
IL-32	Lymphocytes and epithelia		Monocytes			Synergistic with NOD 1 and 2 ligands	
IL-33	Lymphocytes		T helper type 2 lymphocytes			IL-1 receptor induces $T_H2$ responses	
TNF- $\alpha$	Macrophages 17 kD protein		Macrophage activation, endotoxin, phagocytosis	+ + +	Activation of endothelial cells, leukocytes, acute phase protein synthesis, apoptosis	TNF receptor, FADD, MORT, DD	TNF receptor inhibitors, TNF mimetics, COX inhibitors, corticosteroid
TNF- $\alpha$	T lymphocytes 17 kD protein		Antigenic stimulation, mitogen	+ + +	Activation of endothelial cells, leukocytes, acute phase protein synthesis, apoptosis	TNF receptor, FADD, MORT, DD	TNF receptor inhibitors, TNF mimetics, COX inhibitors, corticosteroid
TGF- $\beta$	Fibroblasts, endothelial cells, macrophages, T regulatory lymphocytes	Cystine knot		- - -	Fibrosis, decreased dendritic cell activity, relative decrease in $T_H1$ and $T_H2$ responses, decreased epithelial cell proliferation	TGF- $\beta$ receptor	
IFN- $\gamma$	T lymphocytes, NK cells		Antigenic stimulation or mitogen	- - -	$T_H1$ response, antiviral activity, phagocytosis, induction of MHC I and II expression, MHC	IFN receptor, JAK/STAT signaling	
IFN- $\alpha$	Many cell types	16–20 kD glycoprotein	Virus, double-stranded RNA	- - -	Antiviral activity through MHC I expression oligoadenylate synthetase, Mx proteins	IFN receptor, JAK/STAT signaling	

# Pathologic Basis of Veterinary Disease, 4th Edition

## 4 Chapter 4 Chronic Inflammation and Wound Healing\*

MARK R. ACKERMANN

### 4.1 INTRODUCTION

Chronic inflammation is inflammation of prolonged duration (weeks to months to years) in which acute inflammation, tissue destruction, and tissue repair occur simultaneously. Chronic inflammation arises: (1) when the acute inflammatory response fails to eliminate the inciting stimulus, (2) after repeated episodes of acute inflammation, or (3) in response to unique biochemical characteristics and/or virulence factors in the inciting stimulus or microbe. [Table 4-1](#) lists some of the most common causes of chronic inflammation in domestic animals. The underlying biologic mechanisms that result in chronic inflammation include: persistence/resistance, isolation in tissue, unresponsiveness, autoimmunity, and unidentified mechanisms.

- Persistence/resistance: Persistent infections, such as those caused by *Mycobacterium* spp.; *Nocardia* spp.; deep-seated mycoses, such as *Blastomyces dermatitidis* and *Histoplasma capsulatum*; and parasites, such as *Toxocara canis* larvae, can avoid and/or resist phagocytosis by neutrophils and macrophages—or once internalized in these cells, can prevent fusion with lysosomes or killing by lysosomes. Such microbes also usually do not produce biologic molecules that cause severe tissue injury, but their presence continually incites chronic inflammatory and immune responses. Tissue destruction, granulomatous inflammation, and fibrosis are common sequelae.
- Isolation: Some microbes, such as *Streptococcus* and *Staphylococcus* spp., are not naturally resistant to phagocytosis and/or destruction but are able to isolate themselves from effective innate and adaptive immune responses and from antimicrobial drugs by “hiding” themselves in pus.
- Unresponsiveness: Certain foreign materials are virtually indestructible and therefore are unresponsive to phagocytosis and/or enzymic breakdown. They include plant material, grass awns, silica dust, asbestos fibers, some suture materials, and surgical prostheses.
- Autoimmunity and leukocyte defects: Alterations in the regulation of adaptive immune responses to self-antigens result in autoimmune diseases, such as polyarteritis nodosa, with a chronic inflammatory response. Defects in leukocyte function, as occurs in humans with Wegener's granulomatosis, also result in chronic inflammation.
- Unidentified mechanisms: In some diseases, such as canine granulomatous meningoencephalitis, the cause of chronic inflammation remains unknown.

As the chronic inflammatory response develops, cytokines, chemokines, and other inflammatory mediators are released and incite: (1) active inflammation (chronic to granulomatous with lymphocytes, macrophages, plasma cells, and multinucleated giant cells [MGCs]); (2) tissue destruction (necrosis); (3) proliferation of fibroblasts and deposition of collagen (desmoplasia and/or fibroplasia); (4) angiogenesis and neovascularization (granulation tissue formation); and (5) initiation of wound healing (reepithelialization and tissue repair).

\* See [Appendix 4-1](#) for a listing of the acronyms, terms, and functions of the chemical mediators of inflammation.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 4.2 BENEFICIAL AND HARMFUL ASPECTS OF CHRONIC INFLAMMATION

The body initially responds to injury through acute inflammation. Once the acute inflammatory response fails, chronic inflammation ensues as the body attempts to overcome the inciting stimulus via macrophages and the adaptive immune response. If these responses fail, the stimulus is then “walled-off” with collagen produced by fibroblasts, encapsulating the stimulus and functionally placing it “outside” of the body. Often this response can be beneficial and in time can lead to a return to normal activity. Small granulomas or abscesses in the lung, liver, or even in some areas of the skin, with time, eventually go unnoticed by the innate and adaptive immune systems and do not stimulate pain or mechanical interference to movement or function.

153

154

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 4-1 Selected Examples of Conditions That Can Cause or Lead to Chronic Inflammation in Domestic Animals

Microbial Agents	Toxins	Autoimmune Diseases	Foreign Bodies	Other
Bacteria:	<i>Vicia villosa</i> (Hairy vetch)	Lupus erythematosus	Retained suture	Canine granulomatous meningoencephalitis
<i>Brucella</i> spp.		Allergic contact dermatitis	Plant fibers	Lick granuloma
<i>Mycobacteria</i> spp.:		Irritant contact dermatitis	Silica	Sterile nodular granuloma
canine/feline leprosy		Rheumatoid arthritis	Asbestos	
<i>M. avium-intracellulare</i>		Polyarteritis nodosa	Beryllium	Sperm granuloma
<i>M. bovis</i> tuberculosis atypical (e.g., <i>M. marinum</i> )			Inhaled smoke	Chalazion
<i>Rhodococcus equi</i>			Inhaled dust	Eosinophilic granulomas of dogs, cats, horses (see <a href="#">Table 4-2</a> )
Virus:				
Porcine circovirus				
Fungi:				
<i>Trichophyton</i> spp.				
<i>Microsporum</i> spp.				
<i>Aspergillus</i> spp.				
Protozoa/Parasites:				
<i>Leishmania</i> spp.				
<i>Trypanosoma</i> spp.				
<i>Draschia</i> spp.				
<i>Habronema</i> spp.				

On the other hand, chronic inflammation can be detrimental. The mononuclear leukocyte infiltrates (macrophages, lymphocytes, natural killer [NK] cells) within areas of chronic inflammation take up space and often displace, replace, and sometimes obliterate the structure of the original tissue. At the same time, new blood vessels form, fibroblasts proliferate and deposit collagen, and if the lesion expands, the inflammatory response can affect function of adjacent tissues and/or cells and ultimately the function of the entire organ. For example, chronic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

inflammatory lesions in the skin can result in ulcerations and obliterate adjacent hair follicles. In the lung, they can destroy alveoli, and the lesion can become so severe or extensive that it can impair gaseous exchange. In the brain, chronic inflammation can destroy neurons and glia, elevate the intracranial pressure, and obstruct the flow of cerebrospinal fluid (CSF) within the ventricular system and thus contribute to elevated intracranial pressure.

The extent of debilitation in animals with chronic inflammatory lesions depends on the location of the lesion and extent of tissue involvement. Even very small chronic lesions in the brain can rapidly incite clinical signs through either the destruction of neuroparenchyma or, perhaps, by impairing flow or resorption of CSF. In contrast, some widespread chronic inflammatory lesions—such as those in inflammatory bowel disease of dogs and cats, and Johne's disease of cattle—can involve extensive areas of the intestine and often precede clinical signs (diarrhea) by months or even years. Yet other diseases, such as embolic hepatic or lung abscesses or disseminated tuberculoid granulomas, can be debilitating over time through the loss of parenchymal function and the continual release of inflammatory mediators, such as tumor necrosis factor (TNF) and interleukin (IL)-1, both of which affect temperature and appetite (see [Chapter 3](#)).

In chronic inflammation, the first clinical intervention is to remove the inciting factor, if possible. Thus antibiotics and antifungal drugs are used against bacterial and mycotic infections. Some foreign bodies can be removed surgically, and it may be possible to identify, opsonize, chelate, or sequester immunologic allergens/antigens. Unfortunately, few medical therapies completely resolve certain types of chronic inflammation, especially if granulomas and/or extensive scar tissue has developed. In the future, perhaps surgical debulking of large lesions may be followed by gene or stem cell therapy to effectively eliminate specific types of granulomas, such as those caused by mycobacterial infection.

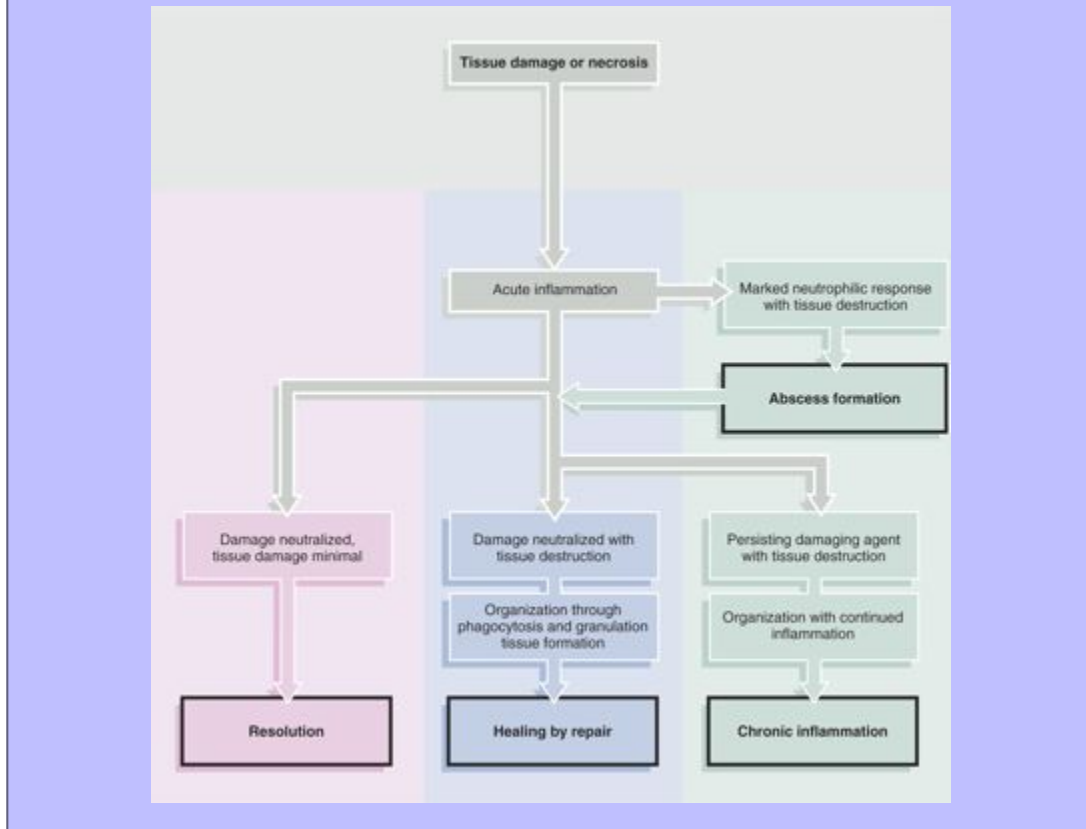

154

155

### 4.3 PROGRESSION OF THE ACUTE INFLAMMATORY RESPONSE TO CHRONIC INFLAMMATION, FIBROSIS, AND ABSCESS FORMATION

Acute inflammatory responses can either fully resolve with return of the tissue to normal structure and function, or repair by healing. If conditions do not allow for complete resolution of the acute inflammatory response, three outcomes can result: (1) progression to chronic/granulomatous inflammation, (2) healing by fibrosis, or (3) abscess formation ([Fig. 4-1](#)). These outcomes are determined by the severity of tissue damage, the ability of cells to regenerate, and the biologic characteristics of the stimulus that caused the injury.

Fig. 4-1 The outcomes of tissue injury and unresolved acute inflammation. (From Stevens A, Lowe JS, Young B: Wheater's basic histopathology: a colour atlas and text, ed 4, New York, 2002, Churchill Livingstone.)

### 4.3.1

#### PROGRESSION TO CHRONIC/GRANULOMATOUS INFLAMMATION

Progression to chronic/granulomatous inflammation occurs when the acute inflammatory response fails (Fig. 4-9). Failure is characterized by: (1) the inciting stimulus persisting for a long period of time (weeks to months); (2) extensive tissue injury and necrosis (third-degree burn); (3) a shift of the cellular elements of the inflammatory response from neutrophils to lymphocytes, macrophages, and sometimes multinucleate giant cells; and/or (4) extensive connective tissue reorganization followed by fibrosis (fibroplasia).

155

156

Deep-seated mycoses, such as *Blastomyces dermatitidis* and *Histoplasma capsulatum*; bacteria, such as *Nocardia*, *Brucella*, *Mycobacterium*, or *Salmonella* spp.; protozoa, such as *Leishmania* or *Trypanosoma* spp.; parasites, such as *Toxocara* larva or *Habronema*; autoantigens, such as those occurring in sperm granulomas or in autoimmune diseases like lupus erythematosus; and foreign bodies (plant awns, sticks, metals, asbestos, and suture material) are examples of stimuli that often result in chronic inflammatory responses. Such agents continually induce the release of inflammatory mediators from indigenous parenchymal cells and leukocytes, leading to macrophage infiltration and activation; T lymphocyte, NK cell, and perhaps mast cell or eosinophil infiltration; and fibroblast and endothelial cell proliferation. Some of the inflammatory cytokines, such as

## Pathologic Basis of Veterinary Disease, 4th Edition

---

transforming growth factor- $\beta$  (TGF- $\beta$ ), may interfere with regeneration of epithelial and parenchymal cells (see Wound Healing and Angiogenesis).

### 4.3.2 HEALING BY FIBROSIS

Healing by fibrosis occurs following tissue injury in which there is necrosis of the tissue framework provided by stromal elements (connective tissue) and of the epithelial cells required to regenerate and successfully reconstitute the parenchymatous elements of the tissue (Fig. 4-27). With necrosis, dead tissue and the acute inflammatory exudate are removed by macrophages (phagocytosis by cells of the monocyte-macrophage system), and the space is filled with fibrovascular tissue (granulation tissue) commonly seen in the healing process. Granulation tissue is eventually replaced by immature fibrous connective tissue that is poorly collagenized and then by mature connective tissue that is well collagenized, healing the wound and forming a scar (cicatrix). Structural integrity may be reestablished, but functional integrity is dependent on the extent of the loss of epithelial cells. For example, with severe skin burns or extensive lacerations, dermal scarring eventually replaces lost tissue and to a limited extent restores structural integrity; however, its functional integrity is extremely limited if the scar reduces the range of motion of the limbs and digits. The degree and extent of fibroblast and myofibroblast proliferation in such wounds is largely dependent upon mediators such as TGF- $\beta$  and interleukin-13 (IL-13). (see Wound Healing and Angiogenesis).

### 4.3.3 ABSCESS FORMATION

Abscess formation (Fig. 4-2) occurs when the acute inflammatory response fails to rapidly eliminate the inciting stimulus and the enzymes and inflammatory mediators from neutrophils in the exudate liquefy the affected tissue and neutrophils to form “pus.” Abscesses can have a septic or sterile origin. Septic abscesses most commonly originate from bacterial infection, whereas sterile abscesses arise from incompletely degraded foreign bodies or from the failure of injected medications to be completely absorbed. Pyogenic bacteria, such as *Staphylococcus* and *Streptococcus* spp., commonly cause septic abscesses. They enter tissue hematogenously or by direct extension from the skin following trauma. The pus within an abscess can range in consistency from serous to purulent to caseous and in color from white, to yellow, to green, depending on the inciting stimulus. The color of the exudate often depends on the pigment produced by the inciting bacterium; for example, yellow exudates caused by abscesses formed by *Staphylococcus* and *Streptococcus* spp., green exudate caused by abscesses formed by *Pseudomonas aeruginosa*, and red exudate caused by abscesses formed by *Serratia marcescens*.

Fig. 4-2 **Abscess formation.** **A**, Abscess, lung, cow. A cut section of lung has numerous abscesses. Note the white-to-gray exudate and how it bulges from the cut surface. **B**, In Fig. 4-2, **A**, the exudate consists of cell debris and a large number of neutrophils admixed with lesser numbers of degenerating macrophages and lymphocytes, and bacteria (the latter not visible with H&E stain). H&E stain. (**A** and **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Initially, after an acute inflammatory response has been established, a newly formed septic abscess site consists of a collection of neutrophils that may not be encapsulated or is surrounded by a “thin” vascularized connective tissue wall. At this point, antibiotics can penetrate the capsule and enter the exudates. If the septic abscess persists, the initial “thin” connective tissue wall surrounding the exudates can mature into a fibrous capsule, which is thick and largely impermeable, in an attempt to “wall-off” the exudates from normal tissue. Abscesses with this response can present serious problems in systemic (hematogenous) or local (topical diffusion) antibiotic treatments. In large abscesses with abundant pus, the pus itself may dilute the antibiotic and further

156

157

## Pathologic Basis of Veterinary Disease, 4th Edition

---

prevent the drug from reaching the optimal concentration required to kill the bacteria. It is for these reasons that larger abscesses are often lanced to drain the pus. Sterile abscesses do not require antibiotics or other drugs to kill the inciting stimulus, but they do require breakdown of the capsule by lancing or some other means.

### 4.4 MECHANISMS OF CHRONIC INFLAMMATORY RESPONSES

#### 4.4.1 $T_H1$ AND $T_H2$ IMMUNOLOGIC RESPONSES AND T REGULATORY CELLS

T lymphocytes expressing CD4+ (T helper cells) and CD8+ T lymphocytes (T suppressor or cytotoxic cells) play important roles in the adaptive immune response. Immunologists use the terms  $T_H1$  and  $T_H2$  as immunological response categories useful in understanding the inflammatory process.  $T_H1$  immunologic responses are generally cell mediated, whereas  $T_H2$  immunologic responses are generally humoral. When CD4+ T lymphocytes bind foreign antigens presented by macrophages and dendritic cells, they release lymphokines that attract leukocytes into the lesion site; some of these cells are directed toward a  $T_H1$  response, whereas others are directed toward a  $T_H2$  response. In addition to macrophages and dendritic cells, B lymphocytes can also present antigens to CD4+ T lymphocytes.

In contrast to CD4+ cells, CD8+ T lymphocytes secrete molecules that kill cells to which they bind. This is a particularly effective defense mechanism if the cell is infected with a virus. The cell will be destroyed before it releases new virions able to infect additional cells. In general, CD8+ T lymphocytes monitor all the cells of the body and will kill any cells that express foreign antigen fragments.

Many chronic inflammatory conditions and their lesions are exacerbated by the presence of poorly degradable exogenous or endogenous antigens. These lesions are usually of long duration, smolder, and often develop insidiously. Initially, lesions are small and undetectable, but they eventually evolve and expand to a size that results in clinical signs and/or makes them detectable via palpation or diagnostic modalities. It is during this insidious phase that dendritic cells, macrophages, and B lymphocytes present antigen to CD4+ T lymphocytes to initiate an adaptive immune response. Dendritic cells are the predominant cell type that presents antigens to naïve CD4+ T lymphocytes, whereas macrophages are the predominant cell type that presents antigens to memory CD4+ T lymphocytes. The biologic characteristics of antigens, including the amount and structure of protein, polysaccharide, and lipid, contribute to whether the resulting T-lymphocyte response will be balanced between a cell-mediated response ( $T_H1$ ) and humoral response ( $T_H2$ ) (Fig. 4-3). However, in many chronic inflammatory conditions, there is often a predominance of either  $T_H1$  type cells (cell-mediated responses) over  $T_H2$  type cells (humoral responses) or vice versa. T regulatory lymphocytes (T reg) and regulatory dendritic cells can affect the strength and the balance of  $T_H1$  and/or  $T_H2$  responses through inhibition of either or both responses (see Effector Cells of the Chronic Inflammatory Response, Lymphocytes).

##### 4.4.1.1 $T_H1$ IMMUNOLOGIC RESPONSES

$T_H1$  immunologic responses often occur in response to: (1) foreign bodies; (2) endogenous antigens, such as those in myelin basic protein (which can occur in murine experimental allergic encephalomyelitis [EAE] and is an experimental model of multiple sclerosis); and (3) endogenous antigens, such as those in intracellular microbes like *Mycobacteria* spp., *Listeria monocytogenes*, *Histoplasma capsulatum*, and *Leishmania* spp. In fact, some immunologists believe that the persistence of many intracellular microbes is caused by an

## Pathologic Basis of Veterinary Disease, 4th Edition

---

inadequate or suboptimal T<sub>H</sub>1 immunologic response or an inappropriately strong T<sub>H</sub>2 immunologic response.

T<sub>H</sub>1 chronic inflammatory responses are composed, histologically, of T and B lymphocytes, macrophages, dendritic cells, and occasionally fibroblasts. They are induced by: IL-12, interferon (IFN)- $\gamma$ , and ILs 18, 23, and 27 (Fig. 4-3). Briefly, antigen presenting dendritic cells release IL-12 (also ILs 18, 23, and 27) that induces pre-T<sub>H</sub>/CD4<sup>+</sup> cells to commit to the T<sub>H</sub>1 pathway. The T<sub>H</sub>1-committed CD4<sup>+</sup> cells then release IL-2 for proliferation of T lymphocytes that produce IFN- $\gamma$  and TNF- $\beta$  which activates macrophages. In addition, IFN- $\gamma$  can inhibit the commitment of pre-T<sub>H</sub>/CD4<sup>+</sup> cells to the T<sub>H</sub>2 pathway.

### 4.4.1.2

#### T<sub>H</sub>2 IMMUNOLOGIC RESPONSES

T<sub>H</sub>2-predominant responses are often seen in chronic inflammatory conditions with an allergic basis, such as asthma, chronic allergic inhalant, or food allergic dermatitis, or inflammatory bowel disease. In addition to increasing the number of T and B lymphocytes, macrophages, dendritic cells, and fibroblasts in the inflammatory milieu, T<sub>H</sub>2 responses can also lead to increased numbers of mast cells and eosinophils associated with IgE and other humoral responses. T<sub>H</sub>2 responses are induced by high concentrations of IL-4, IL-10, also ILs 5, 9, 13, 17, and, to some degree, perhaps ILs 19, 20, 22, 24, 26, 28, and 29 (Fig. 4-3). Briefly, T<sub>H</sub>2 dendritic cells present antigen to pre-T<sub>H</sub>/CD4<sup>+</sup> cells committing them to the T<sub>H</sub>2 pathway. T<sub>H</sub>2-committed CD4<sup>+</sup> cells release IL-4 and ILs 5, 10, 13, 17 and 19 (also ILs 19, 20, 22, 24, 26, 28, and 29) to act on B lymphocytes thus resulting in antibody production and, in some cases, increased activity of eosinophils and mast cells. In addition, ILs 4, 5, 10, and 13 can also inhibit pre-Th/CD4<sup>+</sup> cells from committing to the T<sub>H</sub>1 pathway.

### 4.4.2 GRANULOMATOUS INFLAMMATION AND GRANULOMA FORMATION

Granulomatous inflammation is a distinct type of chronic inflammation in which cells of the monocyte-macrophage system are predominant and take the form of macrophages, epithelioid macrophages

## Pathologic Basis of Veterinary Disease, 4th Edition

(activated macrophages), and MGCs. Granulomatous inflammation occurs secondarily in response to endogenous or exogenous antigens or idiopathically as in granulomatous meningoencephalitis of dogs. 158

Development and regulation of granulomatous inflammation requires multiple factors: (1) an inciting agent, usually with indigestible, poorly degradable, and persistent antigens (e.g., *Mycobacteria* spp.); (2) a host immune response, usually an intense T lymphocyte-mediated response; and (3) the interplay of various cytokines produced by cells within the chronic inflammatory lesion. 159

Classification of granulomatous inflammation by pathologists has evolved over the years because of the increased understanding of disease pathogenesis and advances in molecular biology. For simplicity, this chapter will discuss two morphologic forms of granulomatous inflammation: diffuse (lepromatous) granulomas, which are currently thought to be consistent with a  $T_H2$ -biased immunologic response, and nodular (tuberculoid) granulomas, which are currently thought to be consistent with a  $T_H1$ -biased immunologic response. Both of these types are derived from granulomatous lesions in humans and are increasingly becoming defined and seen as distinct, both immunologically and molecularly.

### 4.4.2.1

#### DIFFUSE (LEPROMATOUS) GRANULOMAS( $T_H2$ -BIASED GRANULOMAS)

*Mycobacterium leprae*, the cause of human leprosy, produces noncaseating aggregates of macrophages and chronic inflammatory cells often around nerve fibres in the distal extremities and upper respiratory tract mucosa (sites in the body with temperatures lower than core body temperature) of infected humans. This type of granulomatous inflammation appears to form with a  $T_H2$ -type bias.

These lesions can be poorly delineated (e.g., poorly defined borders) and have a widespread distribution, a heavy bacterial burden, relatively few lymphocytes, and variable fibrosis. Similar granulomatous lesions are seen in animals. Feline leprosy and canine lepromatous-like granulomas are somewhat similar to human leprosy in lesion formation. *Mycobacterium avium-intracellulare* paratuberculosis—the cause of Johne's disease in cattle, sheep, and goats—also induces a diffuse (lepromatous) type of granulomatous inflammation consisting of diffuse sheets of macrophages with few lymphocytes and plasma cells. This lesion most commonly occurs in the lamina propria of the ileum and colon (Fig. 4-4) and in mesenteric lymph nodes. Special stains, such as an acid-fast histochemical stain and immunohistochemical stains to specific bacterial antigens, can be used to identify these bacteria within the cytoplasm of macrophages (Fig. 4-5). Because bacteria are present in large numbers in these lesions, they are commonly identified by these techniques. Nodular (tuberculoid) granulomas, defined later, are not seen in Johne's disease lesions. Finally, *Mycobacterium avium-intracellulare* infection also occurs in the lung and other organs of birds and other species and induces lesions with similar sheets of macrophages containing abundant bacteria detectable with special stains.

Fig. 4-4 Diffuse (lepromatous) type of granulomatous inflammation, Johne's disease (*Mycobacterium avium-intracellulare* paratuberculosis), ileum, cow. **A**, The mucosa is thickened because of a dense infiltrate of granulomatous inflammatory cells in the lamina propria. **B**, The lamina propria contains numerous macrophages arranged in sheets. The ileal lumen is to the left; scattered crypts still remain in the central area of the specimen. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

159

4.4.2.2

### NODULAR (TUBERCULOID) GRANULOMAS (T<sub>H</sub>1-BIASED GRANULOMAS)

160

Examples of nodular (tuberculoid) granulomas are those that have been classically caused by *Mycobacterium bovis* or *Mycobacterium tuberculosis* and by some deep fungal infections, such as coccidioidomycosis (Fig. 4-6). Tuberculoid granulomas develop with a T<sub>H</sub>1-type bias and occur in many species but have been described extensively from lesions of infected human beings, cattle, and rhesus monkeys. Because the portal of entry is often the respiratory tract, these lesions often involve the lung and other parenchymal organs and induce the formation of granulomas with three distinctive morphologic areas. The innermost area is often, but not always, a centrally located region of cellular necrosis (cell debris and caseation) surrounded by a middle area containing macrophages, epithelioid macrophages, and multinucleate giant cells. The outermost area surrounding the entire lesion consists of T and B lymphocytes, plasma cells, macrophages, and a fibrous capsule.

Mycobacterial organisms and their antigens are very sparse in these granulomas and not commonly detected with acid-fast stains and immunohistochemical stains for mycobacterial antigens. Mineralization can occur in tuberculoid granulomas, but this outcome depends on the species of animal affected. It is common in cattle, present to a lesser degree in pigs, and uncommon in sheep. “Atypical” mycobacteria, such as *Mycobacterium marinum*, can also cause nodular (tuberculoid) granulomas in the subcutaneous tissues of dogs, cats, and other species, and very few organisms are detected with stains.

Microscopically, nodular (tuberculoid) granulomas may or may not have a central core of necrotic cell debris (caseating and noncaseating granulomas) (Fig. 4-6). Those granulomas lacking caseation (noncaseating) often have multinucleate giant cells in the central area in lesions from human beings; however, in granulomatous inflammation of most animals, multinucleate giant cells are often located in the outer area of

## Pathologic Basis of Veterinary Disease, 4th Edition

the inflammation. Still, other granulomas develop this classic morphologic arrangement but do not contain significant infiltrates of macrophages.

**Fig. 4-6 Nodular (tuberculoid) type of granulomatous inflammation, coccidioidomycosis.** Granulomas are round to oval with a central core of numerous macrophages surrounded by lymphocytes, plasma cells, macrophages, and a peripheral zone of fibroblasts, which produce a fibrous capsule. The granuloma on the left contains a single central fungal element (*inset*). H&E stain. (**Figure and Inset**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 4.4.3 CONTENT AND FORMATION OF $T_H1$ AND $T_H2$ GRANULOMAS

$T_H1$  or  $T_H2$  chronic inflammatory responses (Fig. 4-7) and granulomas often can differ somewhat in cellular content (number of  $T_H1$  and  $T_H2$  cells) and the degree of fibrosis. However, for both  $T_H1$  or  $T_H2$  granulomas, roughly 30% to 60% of the T lymphocytes in a granuloma are specific for antigens inducing the granuloma, whether the antigens are from an endogenous or exogenous source, foreign body, or microbe. Co-stimulatory molecules are important for T lymphocyte activation, and the co-stimulatory molecule CD40 ligand is required for recruitment of CD4+ cells into the granuloma and for IFN- $\gamma$  production, whereas granuloma formation is unaffected in mice lacking another co-stimulatory molecule, CD28. CD8+ T lymphocytes can lyse bacteria-infected macrophages containing microbial antigens, thus releasing the organisms and further allowing them to participate in  $T_H1$  or  $T_H2$  responses. The role of  $\gamma/\delta$ -T lymphocytes and NK cells is less clear, but they may have a role in the formation and clearing of either  $T_H1$  or  $T_H2$  granulomas.

Experimentally, schistosome eggs induce  $T_H2$  granulomas in a mouse model, which results in severe fibrosis and eosinophil accumulation (Fig. 4-7). Cytokines of  $T_H2$  bias that are present in the schistosome granulomas include ILs 4, 5, 10, and 13 along with TGF- $\beta$ , resulting in granulomatous lesions with eosinophils.  $T_H2$  cytokines induce Arg-1 activity (metabolism of arginine) in macrophages. The Arg-1 activity results in the

## Pathologic Basis of Veterinary Disease, 4th Edition

production of polyamines, which induce cell proliferation, and proline, which induces collagen production. The presence of fibrosis in this model fits well with parasite-induced granulomas seen in animals and humans; however, it is not a consistent feature of many lepromatous granulomas in animals, such as those in Johne's disease and infections with *Mycobacterium avium-intracellulare*.

*Mycobacterium bovis* antigens induce tuberculoid T<sub>H</sub>1 granulomas. T<sub>H</sub>1 cytokines include IFN- $\gamma$ , IL-12, TNF- $\alpha$ , nitric oxide (NO and its intermediates, NO<sub>2</sub>-, NO<sub>3</sub>-, N<sub>2</sub>O<sub>2</sub>, and ONOO-), and TGF- $\beta$ . In contrast to the Arg-1 pathway used in T<sub>H</sub>2 granulomas, macrophages in T<sub>H</sub>1 granulomas use the nitric oxide synthetase 2 (NOS<sub>2</sub>) pathway to produce nitric oxide and citrulline, which reduces the degree of fibrosis. In granulomas with a T<sub>H</sub>1 bias, the regulation of fibrosis and collagen deposition occurs largely by the influence of IL-13 and TGF- $\beta$ .

160

161

**Fig. 4-7 Mechanistic basis for fibrosis in experimentally induced T<sub>H</sub>1- and T<sub>H</sub>2-mediated responses by macrophages.** In T<sub>H</sub>1-mediated responses, nitric oxide synthetase 2 (NOS<sub>2</sub>) enzyme is activated by interferon- $\gamma$  (IFN- $\gamma$ ), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and interleukin-1 (IL-1) produced by T lymphocytes. The NOS<sub>2</sub> enzyme converts L-hydroxy-arginine to citrulline, which is antifibrotic. With the T<sub>H</sub>2 pathway, NOS<sub>2</sub> is not activated in the presence of the T<sub>H</sub>2 cytokines (ILs 4, 10, and 13) and granulocyte-macrophage colony-stimulating factor (GM-CSF), and ornithine is converted to polyamines and proline, which induce cell proliferation of fibroblasts and collagen production, respectively, thereby contributing to fibrosis. TGF- $\beta$ , Transforming growth factor- $\beta$ . (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

### 4.4.4 SARCOIDOSIS OF HUMAN BEINGS

Sarcoidosis is a disease of human beings characterized by the spontaneous formation of granulomas. To date, no counterpart in domestic animals has been found. However, studies of sarcoid granulomas have led to an improved understanding of granuloma formation that may apply generally to other animal species. Individuals with sarcoidosis develop granulomatous reactions in the lung hilus, lung parenchyma, eye, and skin. The disease appears to be caused by a persistent, ineffective reaction to an unknown antigen in individuals who may have a predisposition to the disease. It begins with an accumulation of antigen-presenting cells, which trigger T lymphocytes to release cytokines important for granuloma formation.

Sarcoid patients have an accumulation of CD4<sup>+</sup> T lymphocytes with receptors for CXC3 chemokines and IL-12, and they release IFN- $\gamma$  and IL-2. There is an expansion of T lymphocytes with TNF receptors, B lymphocyte proliferation with immunoglobulin synthesis, and the accumulation of activated macrophages expressing major histocompatibility complex (MHC) II antigens and adhesion molecules. Macrophages and T lymphocytes have an increased propensity for proliferation in situ. The macrophages release IL-1, IL-6, IL-8, IL-15, TNF- $\alpha$ , granulocyte-macrophage colony-stimulating factor (GM-CSF), regulated on activation, normal T lymphocytes expressed and secreted (RANTES), IP-10, monocyte chemotactic protein-1 (MCP-1), and macrophage inflammatory protein- $\alpha$  (MIP-1- $\alpha$ ), which contribute to macrophage infiltration and activation. In some patients, the macrophages also release fibrogenetic cytokines, such as TGF- $\beta$ , platelet-derived growth factor (PDGF), and insulin-like growth factor, thus inducing fibrosis.

### 4.4.5 SARCOIDS OF HORSES

Sarcoids of horses are not a correlate to sarcoids in human beings. Sarcoids that occur in the skin of horses are not granulomas but are locally aggressive skin tumors, and the most common dermatologic neoplasm reported in horses. They are composed of proliferating fibroblasts and do not contain the numerous macrophages, lymphocytes, and plasma cells seen in human sarcoids. There is no consistently effective therapy for equine sarcoid. Bovine papillomavirus (BPV) types 1 and 2 are associated with the development of equine sarcoid. Most sarcoid tumors express the BPV types 1 and 2 major transforming protein, E5, but appear not to produce infectious virions. E5 may contribute to virus persistence and disease pathogenesis by down-regulating MHC class I expression and thereby reducing immunosurveillance. The mode of transmission of BPV infection has not been determined.

161

162

### 4.4.6 EOSINOPHILIC GRANULOMAS

Certain types of chronic inflammation have dense infiltrates of eosinophils and many of these form eosinophilic granulomas (Table 4-2; also see Chapter 17). Some eosinophilic granulomas develop in response to migrating parasites, such as *Toxocara canis* (larval migrans). In certain other conditions of cats, dogs, and horses, it is suspected that some of these conditions form in response to antigen in a T<sub>H</sub>2-directed manner; however, no specific antigen has been identified for many of these conditions.

Grossly, eosinophilic granulomas in cats appear as papules, nodules, plaques (sometimes linear), and ulcers in the skin. They also occur as nodular or ulcerated lesions in the oral mucosas and footpads. Microscopically, the inflammatory response consists of eosinophils, macrophages, and areas of dense eosinophilia around collagen (Fig. 4-8). For many years, the densely eosinophilic, collagen-rich areas were considered regions of collagen degradation; however, the eosinophilic material is composed largely of major basic protein (MBP), a protein

## Pathologic Basis of Veterinary Disease, 4th Edition

present in large amounts in the granules of eosinophils (see [Chapter 3](#)). Apparently eosinophils degranulate in these regions, releasing MBP, which accumulates over time.

4.4.7

### OTHER CHRONIC INFLAMMATORY/GRANULOMATOUS CONDITIONS

Several conditions of human beings and animals are characterized by chronic inflammatory and/or granulomatous lesions. One such condition, polyarteritis nodosa, is seen in human beings and rats and only rarely in other species. It is characterized by perivascular infiltrates of lymphocytes, plasma cells, and macrophages. Dogs can develop idiopathic canine polyarteritis, a condition in which arterial lesions not only involve coronary arteries, but also medium to small arteries of other organs. As indicated earlier, eosinophilic granulomas occur in cats, dogs, and horses, and the causes of these granulomas have not been determined but are thought to occur secondary to parasitic larval migration, microbial infections, or foreign material. Finally, a variety of other human diseases are characterized by varying degrees of perivascular granulomatous inflammation, but to date have no or very rarely seen veterinary correlates. These diseases occur around blood vessels, may be secondary to immunologic mechanisms, and include: large-vessel vasculitis (giant cell [temporal] arteritis, Takayasu arteritis), medium-sized vessel arteritis (Kawasaki disease, [and polyarteritis nodosa]), and small-vessel vasculitis (Wegener's granulomatosis, Churg-Strauss syndrome, microscopic polyangiitis, Henoch-Schönlein purpura, essential cryoglobulinemia vasculitis, and cutaneous leukocytoclastic angiitis).

Table 4-2 Eosinophilic Granulomas of Domestic Animals

Species	Type of Eosinophilic Granuloma
Feline	Eosinophilic plaque, granuloma, and dermatitis
Canine	Eosinophilic granuloma of the oral cavity of huskies and other dogs
Equine	Equine collagenolytic granuloma, axillary nodular necrosis, unilateral papular dermatosis
All species	Eosinophilic (T <sub>H</sub> 2) granulomas secondary to parasitic infections

4.4.8

### INHIBITION OF MACROPHAGES IN THE CHRONIC INFLAMMATORY RESPONSE

Although macrophage activation is most commonly discussed and studied, macrophages can also be inhibited. For example, macrophage activity is inhibited/reduced after phagocytosis of apoptotic bodies and low-density lipoproteins (LDLs) in some inflammatory foci. In addition, macrophages can be inhibited by several chemical mediators, including IL-10, TGF- $\beta$ , IFN- $\gamma$ , monocyte colony-stimulating factor, CD47, CD200R, CD36,  $\alpha_5\beta_3$ -integrins, and glucocorticoid receptor activation ([Table 4-3](#)). These mediators are often present in inflamed areas and thus can regulate macrophage activity. Recent work has also shown that macrophage activity can also be reduced by acetylcholine (ACh) and peroxisome proliferator-activated receptor (PPAR). Macrophages express ACh receptors, which are ligand-gated ion channels. They are most often associated with the neuromuscular junction and the peripheral and central nervous systems. Vagal release of ACh modulates macrophage activity and TNF- $\alpha$  release. It is termed the “cholinergic antiinflammatory pathway.” Inhibition of macrophage activity can be beneficial in preventing overexuberant activity of the chronic inflammatory response. On the other hand, research may find that inhibition may be detrimental in certain conditions.

162

4.4.8.1

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS: TRANSCRIPTION FACTORS THAT REDUCE CHRONIC INFLAMMATORY RESPONSES

Activated PPARs are nuclear transcription factors that can alter and often reduce inflammatory responses by macrophages, dendritic cells, endothelial cells, and T lymphocytes. The PPARs affect inflammatory responses through transrepression of signal transduction pathways by binding to peroxisome proliferator binding elements (PPBEs) and enhancing transcription or inhibiting transcription factors. PPARs can inhibit NF kappa B, STATs and AP-1, and the T-lymphocyte activator NFAT. Through inhibition of NF kappa B and AP-1 signaling in macrophages, PPAR activity decreases iNOS expression, reduces macrophage survival, and inhibits cytokine (IL-6 and IL-12) and vascular cell adhesion molecule-1 (VCAM-1) expression. Thus PPARs generally inhibit inflammatory activity of chronic inflammatory cells, such as macrophages and T lymphocytes, and thereby prevent overzealous reactions. Agonists to PPARs have promise as therapeutic agents that may reduce the inflammatory response in atherosclerosis and other chronic inflammatory or granulomatous lesions.

4.5

### GROSS AND MICROSCOPIC LESIONS AND NOMENCLATURE OF THE CHRONIC INFLAMMATORY RESPONSE

The term *chronic inflammation* implies two underlying and often concurrently occurring processes: fibroplasia and cellular infiltration. Fibroplasia, the formation of fibrous connective tissue, includes any stage of the process from the formation of fibrous connective tissue that includes newly formed “immature” connective tissue with newly formed blood vessels to “mature” connective tissue that contains well-collagenized and remodeled granulation tissue. Cellular infiltrates are composed of predominantly macrophages, lymphocytes, and plasma cells, depending on the inciting stimulus and the duration of the inflammatory process. It is important to understand the meaning of these terms mechanistically and in the context of developing morphologic diagnoses for gross and histopathologic lesions. To clinicians, these terms imply duration of illness, whereas to pathologists, they imply the characteristics of the tissue's response to injury.

163

164

Grossly, chronic inflammatory lesions are often gray to white, firm, and have either a nodular surface in the case of granulomas or an indented or pitted surface in the case of fibrosis. The gray-to-white color is largely a result of the infiltrates of macrophages and lymphocytes, proliferation of fibroblasts, and deposition of fibrous connective tissue. The firm texture is attributable to fibrous connective tissue (fibroblasts and endothelial cells) and the consolidation (i.e., solidification) of the leukocytes in the exudate. The irregular shape occurs because of the haphazard accumulation of leukocytes and the fibrosis/scarring and contraction of the lesion by myofibroblasts within the fibrous connective tissue (see Wound Healing and Angiogenesis).

The lungs of dogs with *Blastomyces dermatitidis* infection often have a nodular appearance because of the formation of numerous granulomas and/or pyogranulomas (Fig. 4-9). The use of and distinction between terms such as granuloma and pyogranuloma are dependent on the number of neutrophils in the overall inflammatory exudate or in the center of the granuloma and often reflects the interpretation of the examining pathologist.

The kidneys of dogs, cats, or other species with chronic interstitial nephritis or chronic pyelonephritis, for example, frequently have pitted surfaces that correspond to areas where fibrous tissue formed within renal parenchyma during the chronic inflammatory response that pulls the renal capsule into the parenchyma as part of the healing process. In chronic pyelonephritis, the inflammatory bands often radiate from the renal medulla into the cortex and to the renal capsule, and obliterate or surround and separate cortical tubules and glomeruli. Fibrous

## Pathologic Basis of Veterinary Disease, 4th Edition

adhesions between the renal cortex and the capsule can occur. This fibrous connective tissue may also contain lymphocytes, plasma cells, and macrophages.

Grossly, scars, abscesses, and granulomas that occur with the persistence of chronic inflammation are often easily seen. Severe scarring results in an area that is generally gray to white with extensive contraction, whereas abscesses are often round with a fibrous capsule and a central area of pus. Granulomas are often gray to white, round to oval, and firm to hard, whereas diffuse granulomatous inflammation is often gray to white; expansile, but poorly demarcated from adjacent tissue; and firm. Grossly the three main differential diagnoses for a white, firm, oval to irregular nodular mass are abscess, granuloma, and neoplasm. Most commonly, histopathology is required to differentiate the three as they can appear very similar grossly.

**Fig. 4-9 Granulomas and pyogranulomas, blastomycosis, lung, dog. A,** Numerous multifocal discrete and coalescing variably sized gray-white nodules are scattered at random (embolic pattern) in the lung parenchyma. They are composed of granulomatous inflammatory cells. Note that the lung lobes fail to collapse. **B,** The granulomatous inflammatory exudate contains activated and multinucleate giant cells with intracellular *Blastomyces dermatitidis* organisms (arrows). Lymphocytes and plasma cells are also present in the exudate. H&E stain. (A, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. B, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Microscopically, chronic inflammatory responses are classified into categories based on the types and distribution of the inflammatory cells in the exudate. These categories include: (1) chronic inflammation, (2) chronic-active inflammation, (3) granulomatous inflammation, (4) pyogranulomatous inflammation, (5) granulomas, and (6) pyogranulomas.

- The simplest type of chronic inflammation has a basic cellular exudate consisting predominantly of lymphocytes with lesser numbers of macrophages and plasma cells (Fig. 4-10). Sometimes lymphocytes and macrophages predominate over plasma cells, and such lesions can be called lymphohistiocytic. “Histiocytic” is a term used for macrophage infiltration; however, a few pathologists use the term “macrophagic.” This type of inflammatory response is characteristically seen in the early stages of the chronic inflammatory response and in response to specific microbes, such as viruses.
- Chronic-active inflammation has the same cellular components as chronic inflammation, but also contains neutrophils, fibrin, and plasma proteins that are constituents of the acute inflammatory response. Chronic-active inflammation occurs when the inciting stimulus has not been removed from the exudate in the chronic inflammatory response, and it continues to elicit an acute inflammatory response. One should be careful not to confuse the morphologic diagnosis of chronic-active inflammation with the hepatic disease entity of dogs termed chronic-active hepatitis.
- Granulomatous inflammation has a basic cellular exudate consisting predominantly of activated macrophages and perhaps also epithelioid macrophages, multinucleate giant cells, and lesser numbers of lymphocytes and plasma cells. Granulomatous inflammation can be arranged in a diffuse or haphazard manner as seen in the thickened intestinal mucosa (i.e., lamina propria) of cattle with Johne's disease (Fig. 4-4). If the macrophages are arranged in solid, nodular-like masses, they are termed granulomas (see later). Granulomatous inflammation is characteristically seen in deep-seated mycoses; infections with more evolved bacteria, such as *Nocardia*, *Brucella*, and *Mycobacteria* spp., and protozoal infections.
- Pyogranulomatous inflammation has the same cellular exudate as granulomatous inflammation but also contains multifocal/random infiltrates of neutrophils, fibrin, and plasma proteins, which are constituents of the acute inflammatory response. Pyogranulomatous inflammation occurs when the inciting stimulus has not been removed from the exudate in the granulomatous inflammatory response, and it continues to elicit an acute inflammatory response. A nodular-like granulomatous area with neutrophils is termed a pyogranuloma (see later). Pyogranulomatous inflammation is often seen with infections caused by *Blastomyces dermatitidis* (Fig. 4-9).
- Granulomas are a distinct type of granulomatous inflammatory response that occurs when macrophage infiltration is present in a well-defined area and thus forms a distinct mass on gross observation. Granulomas can occur as noncaseating and caseating types. Noncaseating granulomas are often round to oval and composed of numerous macrophages with variable numbers of epithelioid macrophages, perhaps multinucleate giant cells, with a peripheral zone of fibroblasts, lymphocytes, and plasma cells (Fig. 4-6). Caseating granulomas have the same morphologic features as noncaseating granulomas; however, the center is formed by a core of gray-white-yellow pasty (thick-dehydrated) necrotic debris resembling cheese (Latin caseus = cheese). Caseating granulomas most commonly occur in tuberculosis.
- A pyogranuloma is a granuloma with a central area of neutrophils.

**Fig. 4-10 Chronic inflammation, distemper, brain, raccoon.** In its simplest form, chronic inflammation, as seen with some viral infections, consists of an exudate of lymphocytes with occasional macrophages and plasma cells. In many tissues, especially in the central nervous system, these cells can have a perivascular pattern of distribution. In certain animal species (exotic wildlife species, horses) and specific disease categories (parasitic, protozoal, viral), perivascular chronic inflammatory exudates may also contain variable numbers of eosinophils. H&E stain. (Courtesy Dr. J. F. Zachary, College of Veterinary Medicine, University of Illinois.)

### 4.6 EFFECTOR CELLS OF THE CHRONIC INFLAMMATORY RESPONSE

The primary effector cells of the chronic inflammatory response are fibroblasts, macrophages, dendritic cells,  $\alpha$ - $\beta$  and  $\gamma$ - $\delta$  lymphocytes, NK cells, plasma cells, mast cells, eosinophils, and endothelial cells. These cells comprise chronic inflammatory lesions and also mediate adaptive immune responses and tissue repair.

165

#### 4.6.1 FIBROBLASTS

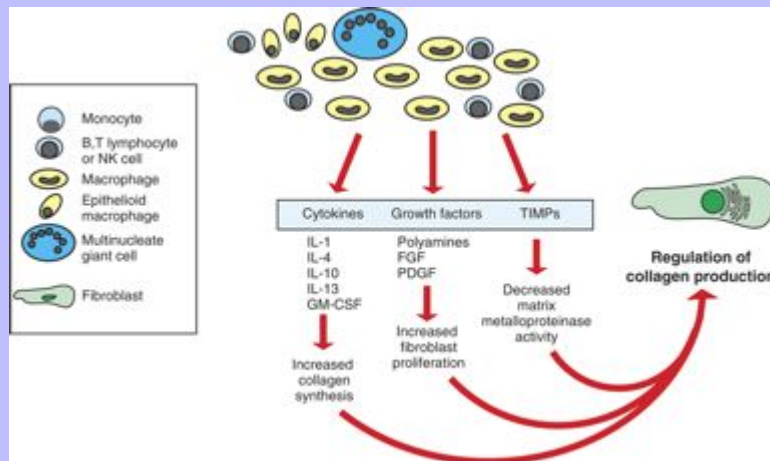

Fibroblasts are multipurpose cells whose function is often overlooked in tissue responses to injury (Figs. 4-11 and 4-12). Fibroblasts are elongated cells that contribute to the structural integrity of tissue and have abundant rough endoplasmic reticulum, which is used for the synthesis of collagen. In addition, they also produce other extracellular matrix (ECM) proteins, cytokines, matrix metalloproteinases, and chemokines that regulate the composition of the extracellular microenvironment in physiologic and pathologic conditions.

166

## Pathologic Basis of Veterinary Disease, 4th Edition

With tissue injury or certain hypoxic conditions, fibroblasts undergo proliferation in response to the release of fibroblast growth factors (FGFs), TGF- $\beta$ , IL-13, PDGF, vascular endothelial growth factor (VEGF), and other mediators/molecules. Continued release of these substances in response to chronic inflammatory stimuli leads to the extensive fibrosis and collagen deposition characteristic of chronic inflammation. The mechanistic basis for fibrosis in experimentally induced T<sub>H</sub>1 and T<sub>H</sub>2 mediated responses by macrophages is illustrated in Fig. 4-7 (also see Fibroblasts and the Mechanistic Basis of Fibrosis).

**Fig. 4-11 Development of fibrosis in chronic inflammation.** In most chronic inflammatory lesions, activated macrophages, lymphocytes and other cells secrete cytokines, growth factors, and tissue inhibitors of matrix metalloproteinases (TIMPs) that lead to fibroblast proliferation and collagen synthesis. FGF, Fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; NK, natural killer; PDGF, platelet-derived growth factor. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

### 4.6.2 MONOCYTES/MACROPHAGES

Along with fibroblasts, monocytes/macrophages are one of the hallmark cell types of chronic inflammation. They produce a wide variety of inflammatory mediators, including chemokines, cytokines, nitric oxide, and are often situated at strategic locations within tissues of the body to: (1) quickly sense the initial activity of acute inflammation, (2) migrate in response to chemotaxins, (3) internalize agents and particulate matter for sequestration/removal, and (4) process antigens for presentation to effector cells of the adaptive immune response.

Macrophages arise from bone marrow-derived monocytes, which circulate hematogenously with some monocytes localizing in tissues physiologically. The differentiation of monocyte stem cells into blood monocytes proceeds rapidly in the bone marrow (i.e., 1½ to 3 days) and is regulated by growth and

## Pathologic Basis of Veterinary Disease, 4th Edition

differentiating factors, cytokines, and adhesion molecules, such as IL-3, colony-stimulating factors, and TNF. Under physiologic conditions, monocytes in the blood localize throughout the body and differentiate into tissue macrophages. Several organs have specialized tissue macrophages, including bone (osteoclasts), liver (Kupffer cells), lung (pulmonary alveolar macrophages and pulmonary intravascular macrophages [in ruminants]), brain (microglial cells), testis (interstitial macrophages), and spleen and lymph node (sinus histiocytes). With acute inflammatory stimuli, monocytes/macrophages typically enter affected tissue within 24 to 48 hours. Certain mediators, such as the chemokine, monocyte/macrophage chemotactic factor (MCP), monocytes recruit from the blood into areas of inflammation. Once present, monocytes rapidly become activated by cytokines, antigens, and other stimuli. In chronic inflammatory lesions, macrophages are the cell of last resort and accumulate in sites of persistent antigen, persistent microbes, foreign material, or repeated injury.

166

167

**Fig. 4-12 Fibroblast, fibrosis in chronic inflammation.** A fibroblast (F) is surrounded by collagen fibrils (C), many of which extend from the fibroblast plasma membrane. Edema fluid also separates many of the fibrils. The fibroblast has a large amount of rough endoplasmic reticulum because of the high level of collagen protein synthesis. Adjacent to the collagen fibers is a modest amount of polymerized fibrin (dark area, bottom of illustration). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

4.6.2.1

### MONONUCLEAR CELL MATURATION AND TRAFFICKING IN THE CHRONIC INFLAMMATORY RESPONSE

The macrophage is a key part of the development and persistence of chronic inflammation. Monocytes, derived from the bone marrow, enter tissues to form the macrophage-monocyte system (e.g., Kupffer cells,

## Pathologic Basis of Veterinary Disease, 4th Edition

alveolar macrophages, and microglial cells) and thus are part of the innate and adaptive immune systems. Monocytes can also be recruited from the blood stream to enter tissue and differentiate into macrophages that can also respond to tissue injury. The population of macrophages in a tissue is maintained by three mechanisms: (1) entry of monocytes from blood, (2) local proliferation, and (3) loss of macrophages when they reach their tissue life span. Under noninflammatory conditions, the replenishment of tissue macrophages occurs through local proliferation and not via monocyte influx. However, with inflammatory stimuli, monocytes are recruited from the blood into tissue in response to the stimulus.

In noninflamed tissue, monocytes expressing CX3CR1 and CCR5 chemokine receptors are attracted to tissues releasing their respective ligands (i.e., fractalkine (CX3CL) and MIP-1- $\alpha$  [CCL3]). In areas of inflammation, monocytes expressing CCR2 chemokine receptors are attracted by MCP-1 (CCL2) (Table 4-4). Attracted monocytes enter these areas in a manner similar to that described for the leukocyte adhesion cascade outlined for neutrophils in Chapter 3. Slow rolling is mediated by L-selectin adherence to L-selectin receptors expressed by endothelial cells. However, firm adherence by monocytes to endothelial cells is largely mediated by LFA-1 (CD11a/CD18), very late antigen-4 (VLA-4) ( $\alpha_4\beta_1$ -integrin), and also Mac-1 (CD11a/CD18) molecules that adhere to the respective endothelial cell ligands: intercellular adhesion molecule (ICAM)-1/2, VCAM-1, and ICAM-1/2, respectively. Transmigration of monocytes between endothelial cells is mediated by leukocyte adhesion molecules expressed on the monocyte such as LFA-1, VLA-4, Mac-1, platelet endothelial cell adhesion molecule-1 (PECAM-1), and junctional adhesion molecule JAM A, JAM B, and JAM C. These molecules bind to adhesion molecules such as PECAM-1 and the JAM molecules expressed by endothelial cells at the intracellular junction. As monocytes and other leukocytes pass between endothelial cells, they separate the tight junctions and VE-cadherins to allow intercellular migration.

### 4.6.2.2

#### ACTIVATION OF MONOCYTES/MACROPHAGES

Activation of monocytes/macrophages occurs in response to various stimuli (Fig. 4-13), each of which incites a slightly different response by the macrophage (Table 4-3). Monocytes/macrophages are activated by stimuli that include the following:

- Innate immune activation during microbial infections through the binding of microbial products (e.g., LPS and teichoic acid) or endogenous molecules (e.g., heat shock proteins and oxidized LDLs) to Toll-like receptors
- Classic activation mediated by IFN- $\gamma$  IL-12, and T helper lymphocyte type 1 responses ( $T_H1$  responses)
- Alternative activation mediated by IL-4 and IL-13 during T helper lymphocyte type 2 responses ( $T_H2$  responses)
- Humoral activation by the attachment of immunoglobulins to Fc receptors and complement factors to complement receptors

167

168

The outcome of these different types of activation leads to specific responses:

- Innate activation can lead to release of reactive oxygen species (ROS), nitric oxide (NO), and IFN- $\alpha$  and IFN- $\beta$ .

## Pathologic Basis of Veterinary Disease, 4th Edition

- Classic activation with IFN- $\gamma$  leads to expression of MHC II antigen, respiratory burst, release of IL-1 and TNF for microbial killing, cellular immunity, and delayed type hypersensitivity.
- Alternative activation enhances MHC class II expression and mannose receptor expression for humoral immunity and allergic responses.
- Innate deactivation and reduced inflammatory responses can occur with the uptake of apoptotic cells or storage of oxidized LDLs in lysosomes.

**Table 4-4 Key Adhesion Molecules and Chemokines Involved with Homing of Naïve Lymphocytes, Adherence/Transmigration of Monocytes, and Activated T Lymphocytes in Sites of Chronic Inflammation**

Cell Type	Endothelial Cell Type	Slow Rolling by the Leukocyte-Endothelial Cell	Chemokine Receptor-Ligand	Firm Adhesion (Leukocyte-Endothelial Cell)	Transmigration

## Pathologic Basis of Veterinary Disease, 4th Edition

---

\* Activated T lymphocyte in this case is a generic term for T<sub>H</sub>1, T<sub>H</sub>0, T<sub>H</sub>2 effector memory and central memory cells, and T-lymphocyte clones.

4.6.2.3

### FORMATION OF EPITHELIOID MACROPHAGES AND MULTINUCLEATE GIANT CELLS

Both epithelioid macrophages and multinucleate giant cells often form in response to foreign bodies or persistent intracellular pathogens. The molecular mechanisms by which epithelioid macrophages and multinucleate giant cells form are poorly understood. It is a fascinating biologic phenomena requiring membrane fusion and integration of the cytoplasm and nuclei of multiple cells. Studies in human patients with sarcoidosis, a special type of granulomatous inflammation in humans (see Sarcoidosis) have elucidated some of the important factors and conditions that contribute to MGC formation. This process involves cytokines, such as IFN- $\gamma$ , IL-3, 4, 13, and GM-CSF; pathogen factors, such as muramyl dipeptide, a peptidoglycan portion of bacterial cells walls; macrophage receptors, such as P2X<sub>7</sub> (a ligand-gated ion channel activated by adenosine triphosphate); integrins (LFA-1 and ICAM-1); CD98 (ligand for the cell-surface lectin galectin-3 and may function with  $\beta_1$ -integrins); macrophage fusion protein receptor (MFPR; CD47 is a ligand); CD44 (binds hyaluronic acid and works in concert with MFPR); and ADAM9 (a disintegrin and metalloproteinase).

168

169

**Fig. 4-13 The roles of activated macrophages in chronic inflammation.** Macrophages are activated by cytokines from immune-activated T lymphocytes (particularly interferon- $\gamma$  [*IFN- $\gamma$* ]) or by nonimmunologic stimuli, such as endotoxin. The products made by activated macrophages that cause tissue injury and fibrosis are indicated. AA, Arachidonic acid; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; TGF- $\beta$ , transforming growth factor- $\beta$ . Also see [Table 4-3](#). (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

4.6.2.4

### HISTOLOGIC CHARACTERISTICS OF MACROPHAGES

Activated macrophages within tissues are relatively large cells histologically (20 to 25  $\mu\text{m}$  in diameter) with abundant, often clear cytoplasm and a single, oval to polygonal, often slightly eccentric, reniform nucleus (Fig. 4-14). With time, activated macrophages can sometimes further differentiate into epithelioid macrophages and MGCs (see Multinucleate Giant Cells).

169

170

**Fig. 4-14 Macrophages, lung, dog.** Cells have abundant cytoplasm and slightly eccentric, often reniform nuclei (*arrows*). Note the small vacuoles in the cytoplasm, probably phagocytosed material. H&E stain. (Courtesy Dr. N. Cheville, College of Veterinary Medicine, Iowa State University.)

4.6.2.4.1

### Epithelioid Macrophages

Epithelioid macrophages are larger than activated macrophages. They have abundant cytoplasm, and the cell membrane occasionally assumes a polygonal to elongated shape forming sheets and thus can resemble to a limited degree squamous epithelium (Fig. 4-14). These cells have diminished phagocytic capacity, but they contain large amounts of RER, Golgi, vesicles, and vacuoles. These latter structures suggest that the main function of epithelioid macrophages involves extracellular secretion; however, the physiologic activity of epithelioid macrophages is poorly understood and requires additional investigation.

4.6.2.4.2

### Multinucleate Giant Cells

MGCs are common elements of granulomatous inflammation. MGCs are syncytial cells formed by the fusion of two or more activated macrophages into one large cell having two or more nuclei (Fig. 4-15). These nuclei can be distributed in the cell in a haphazard manner or aggregated in the center of the cytoplasm. This form is called a foreign body type of MGC (Fig. 4-15). The nuclei can also be arranged in a horseshoelike semicircle at the periphery of the cell. This form is called a Langhans'-type cell (Fig. 4-15). The Langhans'-type giant cell should not be confused with Langerhans' cells, which are dendritic cells (see next discussion) of the skin.

**Fig. 4-15 Multinucleate giant cells, chronic granulomatous inflammation, central nervous system, rabbit.** This focus contains both foreign body-type (*arrows*) and Langhans'-type (*arrowhead*) multinucleate giant cells. H&E stain. (Courtesy Dr. A. Loretto, Ontario Veterinary College, University of Guelph.)

### 4.6.2.4.3

#### Dendritic Cells

Dendritic cells are central to antigen processing, presentation, and the stimulation of adaptive immunity. Functionally, they serve as sentinel cells of the adaptive immune response. Nearly all tissues and organs contain dendritic cells; however, they are most plentiful in tissues that cover the body, such as the skin and the mucous membranes that line the respiratory and alimentary systems. In skin, for example, specialized dendritic cells, termed Langerhans' cells, are present in the epithelium and function to present antigen taken up in the epidermis to inflammatory cells. Langerhans' cells commonly become neoplastic in dogs and form cutaneous histiocytomas, which are benign tumors of the skin that usually have a good long-term prognosis.

Although dendritic cells have some resemblance to macrophages, they have numerous distinct filopodia, which extend from their surface (Fig. 4-16). Increasingly, several subtypes of dendritic cells are being identified (Table 4-5). In general, immature dendritic cells (CD34+) migrate to sites of antigen exposure, take up antigen, migrate to and mature in a lymphoid organ where they present antigen to T and B lymphocytes (Fig. 4-17). This migration process is mediated by chemokines and adhesion molecules, and most dendritic cells enter lymph nodes via the afferent lymphatic vessels in lymph fluid under the influence of chemokines, particularly CCL21. Once in the lymph node, dendritic cells often localize in the parafollicular (T lymphocytes) area in the vicinity of high endothelial venules (HEVs), a site where naïve

170

T lymphocytes enter the node. In this location, dendritic cells activate naïve T lymphocytes. In addition to their activity as antigen presenting cells, dendritic cells also contribute to the inflammatory process through release of chemokines and cytokines; however, there are fewer dendritic cells than macrophages in the body and within inflammatory lesions. Although macrophages also present antigen to naïve T lymphocytes, macrophage antigen presentation is more efficient for memory T lymphocytes than for naïve T lymphocytes, the forte of dendritic cells. Through recruitment of naïve T lymphocytes, dendritic cells contribute to the ongoing persistence of a stimulus in certain chronic inflammatory lesions.

Fig. 4-16 **Dendritic cell.** Note the numerous filopodia that extend from the cell surface (*arrows*). TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. S. Sacco and S. Fach, USDA/ARS-National Animal Disease Center.)

Table 4-5 Subpopulations of Dendritic Cells (DCs) and Activities

DC Subpopulation	Location	Activity	Other
CD8 <sup>-</sup> DCs	T, S, LN, PP, L	↓T <sub>H</sub> 1, ↑T <sub>H</sub> 2, ↓IL-12	Present antigen
CD8 <sup>+</sup> DCs	T, S, LN, PP, L	↑T <sub>H</sub> 1, ↓T <sub>H</sub> 2, ↑IL-12	Present antigen
CD8 <sup>int</sup> DCs	LN	Enter LN via lymphatics	
Langerhans cells	Skin epidermis	Antigen capture	Migrate to LN
Dermal DCs	Skin dermis	Antigen capture	Migrate to LN
Plasmacytoid DCs	T, S, LN, PP	Viruses induce type I IFN	Antiviral activity

*IFN*, interferon; *IL-12*, interleukin-12; *L*, liver; *LN*, lymph node; *PP*, Peyer's S, spleen; *T*, thymus; *T<sub>H</sub>1* and *T<sub>H</sub>2*, T helper cell type 1 and 2 lymphocyte patch; response, respectively.

**Fig. 4-17 Dendritic cell (DC) precursor migration.** In this example, migration to the skin is mediated by chemokine receptors located on the dendritic cell and by chemokine ligands (CCL) in the skin. Eventually, the dendritic cell takes up antigen and migrates to the lymph node under chemokine influence to present the antigen. In the lymph node, the dendritic cell localizes to the parafollicular area and presents antigen to lymphocytes. CCR, Chemokine receptor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HEV, high endothelial venule; IL-4, interleukin-4; MHC, major histocompatibility complex. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

4.6.2.4.3.1

### Tolerogenic dendritic cells

Tolerogenic dendritic cells can suppress immune responses. They accomplish this activity through the sampling of small amounts of self-antigens, harmless environmental antigens, and inciting the deletion of self-reactive T lymphocytes.

### 4.6.2.4.3.2

#### Dendritic cell trafficking

Trafficking immature monocytic dendritic cells express chemokine receptors CCR1 and CCR5 and are recruited by chemokine ligands CCL3 and CCL4 released from lymphocytes and macrophages in tissue. There are several subtypes of dendritic cells, and those dendritic cells that express CD11c antigen express CCR2, which responds to CCLs 2, 7, 8, 12 and 13. After dendritic cells take up antigen and become exposed to an endogenous (e.g., TNF- $\alpha$ ) or exogenous (a ligand for a Toll-like receptor) mediator, the dendritic cell matures and expresses CCR7 (Fig. 4-17). Mature dendritic cells expressing CCR7 migrate from the site of the inflammatory lesion into the vasculature and then spread hematogenously throughout the body until they are recruited by high endothelial venules in the paracortical areas of lymph nodes in which lymphocytes express CCL19 and CCL20. In this location, dendritic cells present antigen and thus contribute to the amplification of the adaptive immune response.

### 4.6.3

#### LYMPHOCYTES

Lymphocytes play a key role in most chronic inflammatory lesions, especially in autoimmune diseases and in diseases with persistent antigen. As with macrophages, lymphocytes enter unresolved areas of acute inflammation within 24 to 48 hours, being attracted by chemokines, cytokines, and other stimuli. Histologically, they are often aggregated around blood vessels and surround granulomas or are distributed haphazardly within injured tissue (Fig. 4-10). In viral encephalitides, lymphocytes are commonly distributed in a perivascular pattern, primarily in the gray matter. In other types of conditions, such as lymphoplasmacytic stomatitis and pododermatitis of cats, lymphocytes and plasma cells are the predominant cell types in the lesions.

### 4.6.3.1

#### $\gamma/\delta$ -T LYMPHOCYTES

$\gamma/\delta$ -T lymphocytes are often the first type of T lymphocyte to arrive in the lesion of chronic inflammation and can contribute to the formation of granulomas. This mechanism is supported by the fact that mice lacking  $\gamma/\delta$ -T lymphocytes have defects in granuloma formation. However, the role of  $\gamma/\delta$ -T lymphocytes in the establishment and persistence of granulomas has not been fully determined. Cattle have high numbers of circulating  $\gamma/\delta$ -T lymphocytes, relative to other T lymphocytes, and are a useful model for assessing the role of  $\gamma/\delta$ -T lymphocytes, in the formation of classic granulomas in *Mycobacterium tuberculosis* and *Mycobacterium bovis* infections and in the formation of diffuse granulomatous lesions in *Mycobacterium avium-paratuberculosis* infections.

### 4.6.3.2

#### $\alpha/\beta$ -T LYMPHOCYTES (CD4/CD8)

$\alpha/\beta$ -T lymphocytes (CD4 and CD8 lymphocytes) enter areas of chronic inflammation and are key to the regulation of the type of adaptive immune response that ensues, albeit a T<sub>H</sub>1, T<sub>H</sub>2, or T<sub>H</sub>0 response of chronic inflammation and/or granuloma formation. Under the influence of cytokines, these lymphocytes can further differentiate into: (1) effector memory lymphocytes, which enter extralymphoid sites; and (2) central memory lymphocytes, which settle into the blood and lymphoid organs. Memory lymphocytes contribute to the persistence of the chronic inflammatory response and granuloma formation.

### 4.6.3.3 B LYMPHOCYTES

B lymphocytes contribute to chronic inflammation in at least two major ways. B lymphocytes can: (1) take up and present antigen and (2) differentiate into immunoglobulin producing cells (plasma cells or immunocytes) that secrete immunoglobulins that can bind to and opsonize antigens facilitating phagocytosis. Certain persistent, poorly degradable antigens, such as those in foreign bodies and in microbes such as *Nocardia* spp., can have eosinophilic proteinaceous aggregates of immunoglobulin on their outer surfaces, which can be seen histologically and are termed Splendore-Hoeppli proteins.

### 4.6.3.4 T REGULATORY LYMPHOCYTES

T regulatory (T reg) lymphocytes can influence the strength and the balance of T<sub>H</sub>1 and/or T<sub>H</sub>2 responses through inhibition of dendritic cells. T regulatory lymphocytes are thought to release IL-10 and TGF- $\beta$  and small amounts of IL-4. This T reg activity appears to inhibit dendritic cells and both T<sub>H</sub>1 and T<sub>H</sub>2

immunologic responses. If T reg lymphocytes are not activated, then dendritic and antigen presenting cells are free to be activated and initiate T<sub>H</sub>1 or T<sub>H</sub>2 immunologic responses.

172

173

### 4.6.3.5 TRAFFICKING OF NAÏVE AND ACTIVATED T AND B LYMPHOCYTES

#### 4.6.3.5.1 Homing of Naïve Lymphocytes via High Endothelial Venules

After formation, naïve T and B lymphocytes traffic (home) to various locations, such as peripheral lymph nodes, lymphoid follicles in the mucosal surfaces of the colon and cecum, Peyer's patches in the mucosal surfaces of the small intestine, and organs such as the spleen. These cells express L-selectin and migrate in the blood and often enter these areas through specialized vessels termed high endothelial venules (HEVs), which are postcapillary venules that have a thick basal lamina, endothelial cells with a plump morphology due to a cuboidal appearance, and abundant cytoplasm. HEVs produce certain chemokines constitutively (CCL19, CCL21, CXCL12, and CXCL13) to attract naïve T and B lymphocytes expressing the corresponding chemokine receptors CCR7 (receptor for CCL19, CCL21) and/or CXCR4 (receptor for CXCL12) and/or CXCR5 (receptor for CXCL13) (Table 4-4). HEVs are located principally in T-lymphocyte zones (paracortical areas of lymph nodes, interfollicular areas of Peyer's patches, and lymph nodes), but some are located in the B-lymphocyte zones, especially the periphery of B-lymphocyte follicles. Both peripheral lymph nodes and Peyer's patch HEVs express the adhesion molecules that mediate T-lymphocyte and B-lymphocyte adherence, including peripheral node addressin ligand for L-selectin, ICAM 1, ICAM-2, VE-cadherin; however, only Peyer's patch HEVs express MAdCAM-1, a receptor for the  $\alpha$ -4/ $\beta$ -7 adhesion molecule expressed by T and B lymphocytes destined for Peyer's patches and enteric lymph nodes, which are key components of the gut-associated lymphoid tissue (GALT).

### 4.6.3.6 ADHERENCE AND TRANSENDOTHELIAL MIGRATION OF ACTIVATED T LYMPHOCYTES

Lesions transitioning into sites of chronic inflammation release chemokines, sphingosine 1-phosphate, and other chemoattractive stimuli that attract and activate T lymphocytes. Although naïve T lymphocytes express high concentrations of L-selectin and the antigen CD45RB, in acutely activated T lymphocytes and in

## Pathologic Basis of Veterinary Disease, 4th Edition

effector/memory T lymphocytes and T lymphocyte clones, L-selectin expression decreases along with expression of the CD45RB antigen. Instead of L-selectin, acutely activated T<sub>H</sub>1 and T<sub>H</sub>2 cells, effector and central memory lymphocytes, and T lymphocyte clones begin to express high to low levels of E- and P-selectin ligands, which bind to E- and P-selectin receptors, which are expressed by endothelial cells activated in sites of chronic inflammation. Lymphocytes adhere to these areas by eventually binding firmly to the vascular wall via adhesions between LFA-1 adhesion molecule expressed on lymphocytes, which binds to ICAM-1 and ICAM-2 expressed on endothelial cells. Lymphocytes transmigrate across the vascular wall by adherence between LFA-1 integrins and the ICAM-1 molecules, JAM molecules, and also contributions from PECAM-1.

4.6.3.6.1

### Natural Killer Cells

Natural killer (NK) cells elaborate cytokines and have cytolytic activity. They are present in chronic inflammatory lesions, but their role varies based on the characteristics of the inflammatory stimulus. NK cells can kill cells recognized as foreign without previous antigen specificity as is required by T lymphocytes. NK cells are activated by type I interferons and IL-12. Similar to T lymphocytes, NK cells can kill cells with perforin and/or granzyme and TNF-related apoptosis-inducing ligand (TRAIL). They also release IFN- $\gamma$ , TNF- $\beta$ , and TNF- $\alpha$ . Because NK cells lack some of the antigenic specificity required for T lymphocytes, they may contribute to autoimmune disease.

Two subsets of human NK cells have been identified according to surface CD56 expression. One type, CD56dim NK cells, are the majority of NK cells and function as effector cells of natural cytotoxicity and antibody-dependent cellular cytotoxicity. In contrast, CD56bright NK cells secrete cytokines that modulate the immune response.

4.6.4

### PLASMA CELLS

Under appropriate stimuli, such as intense antigenic stimulation and B lymphocyte presentation of antigens, B lymphocytes differentiate into plasma cells, which can secrete immunoglobulins that bind to and opsonize antigens and facilitate phagocytosis. Plasma cells form within lymph nodes, mucosal surfaces, and wound sites. The bone marrow also contains a resident population of plasma cells, which can increase in certain disease conditions and must be differentiated from neoplastic accumulations as can occur with multiple myelomas. Bone marrow plasma cells have immediate access to the vasculature. Similarly, plasma cells within the medullary sinus of lymph nodes can enter lymphatic vessels and eventually the blood; however, peripheral blood often contains few plasma cells. In the chronic inflammatory exudate, plasma cells are usually found mixed, although in lesser numbers, with lymphocytes and macrophages. Plasma cells predominate in certain chronic inflammatory conditions, such as inflammatory bowel disease of dogs and cats, lymphoplasmacytic stomatitis and pododermatitis of cats, chronic dermatitis of any domestic animal species, and interstitial nephritis of dogs and cats.

173

4.6.5

### EOSINOPHILS

Different types of chronic inflammatory conditions and granulomas contain a low to high number of eosinophils. Eosinophils are recruited into and stimulated to proliferate within chronic inflammatory exudates by several mediators, most notably IL-5 and eotaxin. In some chronic inflammatory conditions that contain eosinophils, such as human asthma, there is thought to be a T<sub>H</sub>2 shift, resulting in increased concentrations of chemokines such as eotaxin in the tissue. The same result is likely true for other as yet poorly characterized

174

## Pathologic Basis of Veterinary Disease, 4th Edition

---

conditions, such as the eosinophilic complex of cats, eosinophilic infiltrates in the base of the tongue of Siberian huskies and other dogs, eosinophilic enteritis in boxer dogs, and eosinophilic inflammatory lesions in the skin of horses. For these conditions, it may be that some type of persistent yet unidentified T<sub>H</sub>2-inducing antigen is present locally.

### 4.6.6 MAST CELLS

Mast cells tend to look similar to macrophages in hematoxylin and eosin (H&E) stained tissue sections and therefore are often not considered to be a part of the chronic inflammatory lesion. However, when special stains, such as a Giemsa stain, are applied to foci of chronic or granulomatous inflammation, these lesions frequently contain a surprisingly large number of mast cells identified by their characteristic metachromatic granules. For example, chronic lung lesions (e.g., fibrosis and alveolar epithelial hyperplasia) that develop following severe *Mannheimia haemolytica* pneumonia often contain increased numbers of mast cells and reduced levels of substance P fibers (see [Chapter 3](#)).

The reason for the presence of mast cells in chronic inflammatory conditions likely relates to their production of proteolytic enzymes, such as chymase and tryptase. Such enzymes likely help physiologically in remodeling and fine-tuning components of the ECM. With persistent inflammation and fibrosis, there can be increased proliferation of mast cells. In addition to the increased mast cell numbers present in the subacute and chronic phases of *Mannheimia haemolytica* pneumonia, mast cells are also increased in areas of fibrosis. Increased mast cell numbers in these lesions occur by increased infiltration and also by increased proliferation of mast cells in situ. With severe inflammation, there can be loss of substance P fibers, and mast cells can respond to this loss by increasing their expression of c-kit, an important regulator of mast cell proliferation.

### 4.6.7 ENDOTHELIAL CELLS

Endothelial cells are required for neovascularization of chronic inflammatory lesions. The process of angiogenesis (neovascularization) in chronic lesions is similar to that which occurs during wound healing (see Wound Healing and Angiogenesis) and is induced by hypoxia and release of endothelial cell growth factors, such as FGF, VEGF, and PDGF.

Endothelial cells are interconnected by tight junctions composed of occludins, claudin, and JAMs along with adherens junctions composed of vascular endothelial cadherin (VE-cadherin). As leukocytes migrate between endothelial cells, leukocyte adhesion molecules bind some of these intercellular molecules. For example, LFA-1 molecule (CD11- $\alpha$ /CD18) binds JAM-A, VLA-4 molecule ( $\alpha$ -4/ $\beta$ -1) binds VCAM-1 and JAM-B, and Mac-1 (CD11b/CD18) binds JAM-C to mediate leukocyte passage between endothelial cells. These molecules are especially important for the transmigration of monocytes and lymphocytes through endothelial cell junctions into sites of chronic inflammation by providing a stable yet temporary site of attachment of leukocyte filopodia and lamellipodia.

### 4.7 WOUND HEALING AND ANGIOGENESIS

Almost immediately after a wound develops, the process of healing begins. Injured tissue goes through four temporal phases to repair the wound: hemostasis, acute inflammation, proliferation (granulation), and remodeling (maturation, contraction) ([Fig. 4-18](#)). These phases occur in this sequence but may progress at different rates. Even in one lesion site, different areas may be in different phases of repair.

## Pathologic Basis of Veterinary Disease, 4th Edition

Hemostasis occurs immediately after injury unless there is a clotting disorder. Initially following injury, hemostasis is controlled via vasospasm, a process in which blood vessels constrict in response to injury. But this spasm subsides rapidly, and the injured (transected) blood vessels will subsequently relax, allowing additional bleeding if platelets do not become involved. During the initial period of vasoconstriction, platelets aggregate and adhere to exposed collagen, especially collagen in the basement membrane underlying injured endothelial cells. Once adhered, platelets secrete vasoconstrictive substances to: (1) maintain constriction of the transected vessels, (2) initiate the process of thrombogenesis to “plug” the leak in the vessel and prevent additional bleeding, and (3) initiate blood vessel healing (angiogenesis). This process also occurs with large blood vessels, but additional physiologic factors are involved, such as blood shunting and decreased blood pressure.

174

175

**Fig. 4-18 Temporal phases of wound healing (see text for more detail). (Modified from Clark RAF: *Wound repair*. In Clark RAF, editor: *The molecular and cellular biology of wound repair*, ed 2, New York, 1996, Plenum Press.)**

By 24 hours after vascular injury, the inflammation phase (acute inflammation) of wound healing is fully established and can last up to 96 hours or longer if the healing process is disrupted by infection, trauma, or some other perturbation. It is in this phase that the “cardinal signs of inflammation—redness, swelling, heat, and loss of function” are observed (see [Chapter 3](#)). Neutrophils and macrophages, through phagocytosis and their degradative enzymes, breakdown and remove (“clean up”) the cell debris resulting from tissue injury. Macrophages secrete a variety of chemotactic and growth factors that establish the microenvironment for the proliferation (granulation) phase. See [Chapters 2 and 3](#) for greater detail about hemostasis and acute inflammation, respectively.

The proliferation phase begins approximately 4 days after injury and can last up to 3 to 4 weeks or longer depending on the size of the wound. This phase is characterized by the generation of new endothelium (angiogenesis), epithelium (epithelialization), and connective tissue stroma (fibroplasia/desmoplasia) to restore normal structure and function to the injured tissue. The healing of skin following third-degree burns or severe ulcerations is an excellent example of this process. The return to normal structure and function is dependent on: (1) the retention of normal stromal elements of the ECM to provide the structural framework for repair, and (2) normally functioning fibroblasts, myofibroblasts (contractile fibroblasts), endothelial cells, pericytes (nonendothelial components of blood vessels), and epithelial cells.

The remodeling (maturation, contraction) phase begins approximately 3 to 4 weeks following injury, but only after the inflammation and proliferation phases have been successfully completed. This phase includes remodeling of granulation tissue by immature connective tissue and the conversion of immature connective tissue to mature

## Pathologic Basis of Veterinary Disease, 4th Edition

---

connective tissue through extracellular collagen formation. Remodeling can last for 2 or more years. It essentially provides the time some tissues and organs, such as bone, need to return to the near normal tensile strength as required for normal axial and appendicular skeletal function.

A key component of wound repair is the ECM and stromal stem cells (fibroblasts, myofibroblasts) (Fig. 4-19). In mild or moderate injury, partially degraded collagen, proteoglycans, and elastin are completely degraded by matrix metalloproteinases and other enzymes removed by macrophages and then resynthesized by surviving fibroblasts. Simultaneously, fibroblasts and endothelial cells proliferate to fill tissue defects (granulation tissue) and epithelial cells, endothelial cells, and some parenchymal cells proliferate along basement membranes to restore the normal structure of the tissue. If basement membranes are degraded in the injury and the healing process disrupted, then complete healing is delayed because of a requirement for a new basement membrane to be deposited by endothelial cells that attach to and line the contiguous remaining basement membrane. Should healing be continually delayed (infection) or prevented (large tissue defect with loss of stroma and basement membrane), then dysregulated healing can occur in the form of extensive fibrosis (scars and hypertrophic scars) with haphazard arrangement and/or metaplasia of the overlying epithelial cells.

The four phases of wound healing described are applicable to all tissues and organ systems, but each system has its unique mesenchymal and parenchymal cell types that influence the process of healing. Bone healing with callus formation and skin healing with reepithelization are good examples of healing and the specialization of cell types involved (see Chapters 16 and 17). Overall the success of wound healing, especially in the skin, is often determined by whether the process occurs via first or second intention healing. Healing in other tissue is similar. In bone, for example, optimal healing occurs in bone fragments that are stabilized and in direct apposition.

### 4.7.1 FIRST AND SECOND INTENTION HEALING

First intention healing in skin occurs when the edges of a wound site are directly apposed and reattach and heal to each other rapidly. Wounds lacking such close, intimate apposition are termed second intention healing. In the simplest type of wound, such as a cut or incision in the skin by a surgeon, there is initial hemorrhage from the damaged vasculature and retraction and constriction of blood vessels. In the wound area, there is deposition of fibrin, leakage of plasma proteins, clot formation, platelet aggregation, and neutrophil infiltration. The nature of repair is dependent upon several factors, including the proximity of the cut edges to each other, the presence or absence of foreign bodies or infectious microbes, and the general health capacity of the animal to repair wounds. Under ideal conditions, such as in surgery, first intention healing is desired (Fig. 4-20). First intention healing occurs in nonseptic wounds, whereas second intention healing occurs in septic wounds, with foreign bodies, or gaping wounds with nonopposed edges. If the wound healing process is disrupted or delayed, the process is shifted to second intention healing.

175

176

**Fig. 4-19 Extracellular matrix (ECM).** Major components of the ECM include collagens, proteoglycans, and adhesive glycoproteins. Both epithelial and mesenchymal cells (e.g., fibroblasts) interact with ECM via integrins. To simplify the diagram, many ECM components (e.g., elastin, fibrillin, hyaluronan, and syndecan) are not included. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 4.7.1.1

#### FIRST INTENTION HEALING

First intention healing occurs in 2 to 3 days in the skin, if the cut edges of a nonseptic wound are positioned in close proximity to each other by sutures or bandages. During this time, the hemorrhage, plasma proteins, and cell debris within the wound are phagocytosed and removed by macrophages, new blood vessels sprout and grow into the lesion, and the ECM is synthesized to fill the gap between the apposed tissue edges. With time (weeks), this stable interconnection in the dermis will be replaced by collagen fibers that undergo continual maturation, thus providing the skin with near normal tensile strength after wound healing. Concurrently, basal cells of the squamous epithelium will undergo hyperplasia and cover the defect in 3 to 5 days. This type of repair leaves little trace of the wound, except for perhaps mild fibrosis in the superficial dermis and loss of adnexa (e.g., hair follicles, sebaceous glands, and sweat glands) at the site of the wound. The tensile strength is nearly the same as that of adjacent tissue. First intention healing is the goal of the surgeon for repair of incision sites made during surgery.

### 4.7.1.2

#### SECOND INTENTION HEALING

Second intention healing occurs when the cut edges of the skin, for example, are not brought into appropriate apposition for healing (Fig. 4-20). In such wounds, connective tissue is haphazardly synthesized and arranged and there is little or no organization in the healing process; however, fibrous connective tissue fills the defect in the superficial and deep dermis. This disorganization can also delay or prevent the migration of

## Pathologic Basis of Veterinary Disease, 4th Edition

epithelial cells that attempt to cover the surface of the wound and disrupt the orderly deposition of ECM in the wound. In addition, new fibrous connective tissue will lack adnexa (hair follicles, sebaceous and sweat glands). In some cases, fibrous connective tissue can form into granulation tissue (see later section) in which histologically, proliferating fibroblasts are arranged perpendicular to new capillaries, and the long axes of the new capillaries are arranged perpendicular to the surface of the skin (Fig. 4-28, B). Tensile strength of granulation tissue is diminished and the lesions can tear or split. Thus with second intention healing, the site can remain ulcerated, lack hair, and in some cases, the fibrous connective tissue can undergo continuous proliferation and protrude from the skin surface as a hyperplastic scar.

176

177

**Fig. 4-20 Wound healing.** Steps in wound healing by first intention (*left*) and second intention (*right*). Note large amounts of granulation tissue and wound contraction in healing by second intention. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

### 4.7.2

#### IMPAIRED WOUND HEALING

In addition to spontaneously occurring impairments of wound healing, such as foreign bodies, infection, and neoplasms, certain other conditions can prevent or impair wound healing, even first intention healing. For

## Pathologic Basis of Veterinary Disease, 4th Edition

example, altered deposition of collagen and ECM proteins can occur with osteogenesis imperfecta because of impaired production of type I collagen. Similarly, impaired synthesis, cross-linking, hydroxylation, or posttranslational processing of collagen can delay wound healing in individuals with Ehlers-Danlos syndrome. Hyperglycosylation of proteins, which can occur with prolonged diabetes mellitus, can alter the vasculature, lead to diabetic ulcers, and inhibit wound healing.

177

178

Chemotherapeutic drugs can also prevent cellular proliferation and may reduce healing. Several new chemotherapeutic drugs specifically target endothelial cell proliferation, which may greatly influence the process of neovascularization so vital to efficient wound repair. In human beings, guinea pigs, and other species that require dietary vitamin C, deficiencies in intake can lead to scurvy, a disease in which there is decreased collagen hydroxyproline synthesis and poor wound healing. Extreme starvation, malnutrition, and cachexia from cancer or severe weight loss from chemotherapy can impair the synthesis and deposition of ECM proteins as a result of negative energy balance and a lack of amino acid substrates, normally synthesized in the liver. Additionally, such individuals and severe burn victims often lack adequate levels of serum proteins such as albumin, which results in lowered osmotic plasma pressure, impaired fluid resorption from the wound site, and enhanced edema fluid accumulation.

**Fig. 4-21 Hypoxia-inducing factor (HIF).** Initiation of wound healing and regulation of gene expression by HIF. When oxygen levels are normal, HIF is not active, and hypoxia responsive genes are not activated. With hypoxia, however, HIF activates transcription of genes of the hypoxia response elements (HRE). *UB*, *Ubiquitin*; *VHL*, von Hippel-Lindau disease. These genes increase blood vessel formation, iron sequestration, and hypoxia metabolism. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 4.7.3 EXPRESSION OF GENES RESPONSIBLE FOR WOUND REPAIR

Wound repair requires activation of genes of the viable cells, such as macrophages, fibroblasts, and endothelial cells adjacent to the sites of tissue injury. As indicated, macrophages internalize through phagocytosis cell debris to “clear up” an area and degrade the ECM. In concert with fibroblasts, macrophages release growth factors that enhance the proliferation of: (1) endothelial cells for neovascularization, (2) fibroblasts for deposition of a new ECM, (3) myofibroblasts for wound contraction, and (4) parenchymal cells for return to normal structure and function of the affected tissue.

Gene expression by cells in a wound is regulated to a large degree by oxygen levels. In the milieu of a wound, there is generally a reduced oxygen tension caused by vascular damage. Normal tissues have oxygen levels >90% oxygen saturation, and there is increased activity of prolyl hydroxylase, an enzyme that places a hydroxyl group on hypoxia-inducing factor- $\alpha$  (HIF- $\alpha$ ) (Fig. 4-21). Hydroxylated HIF- $\alpha$  is degraded by the ubiquitin pathway. In hypoxic tissue, however, as occurs in wounds or within neoplastic masses, there is reduced prolyl-hydroxylase activity and thereby less hydroxylation of HIF- $\alpha$ . Nonhydroxylated HIF- $\alpha$  aggregates with HIF- $\beta$  and induces transcription of hypoxia responsive elements (HREs) in the genome. The HREs include genes for glycolytic enzymes, growth factors, and iron binding proteins. Early growth response gene 1 (EGR-1) is another transcription factor activated in wounds that leads to expression of growth factors and cytokines. Therefore both HIF- $\alpha$  and EGR-1 activity in hypoxic conditions lead to increased cellular transcription that up-regulates genes for glycolysis (glucose transporters, hexokinase 1 and 2, lactate dehydrogenase, phosphofructokinase), endothelial and fibroblast proliferation (TGF- $\beta$ , VEGF), and iron sequestration (ceruloplasmin, transferrin receptor). These genes promote cell survival in hypoxic conditions, enhance cell proliferation, especially of cells vital to repair (endothelial cells, fibroblasts), and delay or alter differentiation of other cells (epithelia or parenchymal cells) until endothelial and fibroblast proliferation is well established.

178  
179

### 4.7.4 DEGRADATION OF CELLS AND TISSUE COMPONENTS IN WOUNDS

Wounds generally have a central core that is composed of: (1) degenerate and/or necrotic cells, such as parenchymal cells, fibroblasts, and endothelial cells as well as infiltrating leukocytes, such as neutrophils, platelets, lymphocytes, mast cells, and macrophages; (2) inflammatory products (cytokines, eicosanoids, chemokines, and their respective receptors); (3) serum proteins (albumin, acute phase proteins, complement); (4) clotting proteins (fibrin); and (5) ECM. Many of these cells and mediators need to be removed before optimal healing will take place. Phagocytic cells, such as neutrophils and macrophages, are very important in the clean-up process through phagocytosis of particulate matter and subsequent lysosomal degradation and the release of digestive enzymes into the tissue. In addition, macrophages have a major role in the uptake of apoptotic cells that form in response to TNF- $\alpha$  or other proapoptotic inflammatory stimuli. The ECM can be especially difficult to degrade. However, macrophages and fibroblasts are key to this process through the release of matrix metalloproteinases that degrade the ECM.

#### 4.7.4.1 DEGRADATION OF THE EXTRACELLULAR MATRIX IN WOUNDS

The ECM is composed of: (1) proteins and (2) the hydrated gel of proteoglycans in which they lie. It surrounds and interconnects cells in connective tissue, such as fibroblasts, blood vessels, lymphatic vessels, resident mast cells, macrophages, dendritic cells, and nearby parenchymal cells and/or epithelia (Fig. 4-19). The ECM influences cellular development, polarity (organization), and function of epithelial cells (Fig. 4-22).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

With tissue injury, there is often destruction and degradation of the ECM. This process occurs through physical separation or tearing, dilution from plasma proteins, infiltration by inflammatory cells, and degradation by enzymes, largely the matrix metalloproteinases (MMPs) (Fig. 4-23). Macrophages, fibroblasts, mast cells, and most leukocytes produce MMPs (Table 4-6). Many MMPs were initially named after the type of ECM protein that they were found to degrade (e.g., collagenase), but because the MMPs are now known not to be uniquely specific for a particular ECM substrate, they have been reclassified in a numerical manner, matrix metalloproteinases 1 through 20.

For example, collagenase is now termed MMP-1, gelatinase is MMP-2, stromelysin is MMP-3, and matrilysin is MMP-7. Matrix metalloproteinases degrade collagen, gelatin, elastin, aggrecan, versican, proteoglycan, tenascin, laminin, fibronectin, and other ECM components. The MMP enzymatic domain contains three histidine residues that form a complex with zinc. A regulatory domain is responsible for latency and allows activation in the presence of zinc. MMP activity is also regulated by tissue inhibitors of MMP (TIMP). In addition to MMP, serine proteases, such as tissue plasminogen-activator (tPA) and urokinase plasminogen activator (uPA) degrade and remodel ECM components (Box 4-1). Fragments of proteins degraded by MMP, tPA, uPA, and other degradative processes are removed from wounds by lymphatic drainage and phagocytosis by macrophages and neutrophils. Proteoglycans are largely degraded by lysosomal enzymes of macrophages and neutrophils (Box 4-1).

### 4.7.5 RESYNTHESIS OF THE EXTRACELLULAR MATRIX WITH WOUND HEALING

#### 4.7.5.1 SYNTHESIS OF COLLAGEN AND MATRIX PROTEINS

As wounds repair, the body attempts to reestablish the ECM. The structural proteins of the ECM include several types of collagens, elastin, and adhesive types proteins including fibronectin, laminin, tenascin, and vitronectin (Fig. 4-19). The fibrillar collagens (types I, II, III, V, and XI) are triple-stranded helical structures aggregated into fibrils in the extracellular space and surrounded by collagens IX and XII, which interconnect the collagen fibrils with one another and the ECM. Most tissues have a predominance of one collagen type.

179

For example, collagen type I is present in bone, skin, and tendon; collagen type II is present in cartilage and vitreous humor; collagen type III is present in skin and muscle; collagens type V and VI are present in interstitial tissues; collagen type VI is present near epithelia; collagen type VIII is present near endothelial cells; and collagens type X and XI are present in cartilage.

180

Fig. 4-22 **Extracellular matrix (ECM) regulation of cell functions.**

Mechanisms by which ECM (e.g., fibronectin and laminin) and growth factors can influence cell growth, motility, differentiation, and protein synthesis. Integrins bind ECM components and interact with the cytoskeleton at focal adhesion complexes (protein aggregates that include vinculin,  $\alpha$ -actin, and talin). This can initiate the production of intracellular messengers or can directly mediate nuclear signals. Cell-surface receptors for growth factors may activate signal transduction pathways that overlap with those activated by integrins. Collectively, these are integrated by the cell to yield various responses, including changes in cell growth, locomotion, and differentiation. (From Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

Collagen type IV is largely present in basal lamina along with laminin, entactin, a heparin sulfate proteoglycan, and perlecan. Throughout the ECM are molecules of elastin, which stretch, recoil, and allow flexibility in the tissue. Collagen fibers, laminin, fibronectin, tenascin and other ECM proteins bind to cells in the connective tissue via extracellular domain of integrin molecules of cells by means of a specific amino acid sequence, the RGDS sequence. For example, laminin binds  $\alpha_2\beta_1$ -integrins of endothelial cells, some

## Pathologic Basis of Veterinary Disease, 4th Edition

collagens bind  $\alpha_6\beta_1$ -integrins of epithelial cells, and fibronectin and vitronectin bind  $\alpha_5\beta_3$ -integrins. The intracellular portion of integrin molecules interact with the cellular cytoskeleton (i.e., actin assembly) and thereby link the extracellular milieu with cellular activities, such as cell growth, differentiation, proliferation, and senescence (Fig. 4-22).

**Fig. 4-23 Matrix metalloproteinase activities.** Four mechanisms are shown: 1, regulation of synthesis by growth factors or cytokines; 2, inhibition of synthesis by corticosteroids or transforming growth factor- $\beta$  (TGF- $\beta$ ); 3, regulation of the activation of the secreted but inactive precursors; and 4, blockage of the enzymes by specific tissue inhibitors of metalloproteinase (TIMPs). ECM, Extracellular matrix; EGF, epidermal growth factor; IL-1, interleukin-1; PDGF, platelet-derived growth factor. (Modified from Matrisian LM: Trends Genet 6:122, 1990.)

Galactosidases—degrades dermatans and keratans

4.7.5.2

### COLLAGEN PRODUCTION BY FIBROBLASTS

Fibroblasts are induced by TGF- $\beta$  and other cytokines to synthesize collagen (see later). Ribosomes in fibroblasts produce approximately 30 types of collagen  $\alpha$ -chains that are composed of repetitive glycine-x-y segments. Although within the rough endoplasmic reticulum, proline and lysine residues in these chains are hydroxylated, and this hydroxylation process requires vitamin C (Fig. 4-24). The chains are then glycosylated, arranged in a triple helix, and eventually released into the extracellular space as procollagen. The ends of procollagen are cleaved enzymatically resulting in the formation of fibrils termed tropocollagen. Cross-linkages between collagen fibrils occur at lysine and hydroxylysine residues through the activities of the enzyme lysyl oxidase, and this cross-linking process provides the tensile strength of collagen.

4.7.5.3

### SYNTHESIS OF PROTEOGLYCANS

Proteoglycans are produced by fibroblasts. They retain water and are vital to the hydration of the ECM. Proteoglycans have a protein backbone surrounded by a network of glycosaminoglycan (GAG) chains. The GAGs are negatively charged, often highly sulfated, polysaccharide chains covalently linked to the serine residues on a protein backbone (Fig. 4-25). Most GAGs contain high concentrations of N-acetylglucosamine.

## Pathologic Basis of Veterinary Disease, 4th Edition

Hyaluronic acid lacks sulfation and is not connected to the protein backbone (Table 4-7). GAGs are key to the water retention properties of proteoglycans. Proteoglycan hydration of the ECM allows tissue to be pliable and have elasticity.

181

Heparan sulfate proteoglycans such as syndecan, decorin, and perlecan encircle and surround cells and basal laminae. Syndecan is an integral transmembrane protein that can bind chemokines. With inflammation, syndecan can release the chemokine, which then induces leukocyte infiltration.

182

## Pathologic Basis of Veterinary Disease, 4th Edition

4.7.6

### FIBROBLASTS AND THE MECHANISTIC BASIS OF FIBROSIS

Fibroblasts align along planes of tissue stress during development (Langer's lines or tension lines). In quadrupeds, these lines are generally dorsoventral over the thorax and abdomen (axial body plane) and parallel to the long axis of the limbs (appendicular body plane). Surgical incisions along Langer's lines extend between, rather than transect, bands of fibrous connective tissue and tend to pull the margins of surgical skin incisions together. Such incisions reduce the degree of postsurgical scar formation.

Fibroblasts of cats appear to be especially responsive to injury and inflammation. In fact, injury of fibroblasts has been associated with their neoplastic transformation in cats. For example, traumatic lens rupture can lead to intraocular inflammation and fibroblast proliferation, and in some cases, fibrosarcomas. In addition, fibroblast proliferation and fibrosarcomas are common in cats at vaccination sites.

Initially during the hemostasis and inflammation phases of wound repair, fibrin and serum proteins form a loose gel-like framework for the migration of fibroblasts and endothelial cells into the wound to form granulation tissue. Simultaneously, leukocytes and other cells, such as fibroblasts and endothelial cells, are stimulated by HIF- $\alpha$  and epidermal growth factor (EGF) (see Expression of Genes Responsible for Wound Repair) to synthesize and release a variety of growth factors that result in fibroblast proliferation and migration. These factors include FGF-1 and FGF-2, PDGF, EGF, and TGF- $\beta$ -1, 2, and 3. FGF, PDGF, IL-13, and TGF- $\beta$  induce fibroblasts to produce collagen, whereas FGF, VEGF, TGF- $\beta$ , angiopoietin, and mast cell tryptase induce endothelial cells to proliferate and migrate and produce basement membrane for formation of new capillaries.

182

183

Table 4-7 Composition and Tissue Specificity of Selected Glycosaminoglycans (GAGs)

GAG	Carbohydrate Components	Localization
Hyaluronate	Hyaluronic acid	Synovial fluid, vitreous humor, extracellular matrix of connective tissue
Chondroitin sulfate	D-glucuronate +N-acetylgalactosamine	Cartilage, bone, heart valves
Heparan sulfate	Glucuronate +glucosamine	Basement membranes, cell surfaces, intracellular granules of mast cells
Heparin	Glucuronate +glucosamine	Lines arteries of lungs, liver, skin
Dermatan sulfate	L-idurante +N-acetylgalactosamine	Skin, blood vessels, heart valves
Keratan sulfate	Galactose +N-acetylglucosamine	Cartilage, aggregated with chondroitin sulfate

Fig. 4-26 **Transforming growth factor- $\beta$  (TGF- $\beta$ ) signaling.** This process results in fibroblast and myofibroblast activation and collagen deposition *R*, Receptor. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

With time the newly formed, provisional, connective tissue is remodeled into a more mature matrix. In the entire process, TGF- $\beta$  has a central role in fibroblast activity and collagen deposition, because it is produced by platelets and macrophages and induces macrophage chemotaxis, fibroblast migration and proliferation, and synthesis of collagen and ECM proteins. TGF- $\beta$  binds TGF- $\beta$  receptor II, which dimerizes with TGF- $\beta$ RI. The TGF receptor then phosphorylates R-SMAD and Co-SMAD to overcome inhibition of SMAD 7 (Fig. 4-26). This signaling process induces fibroblast activity, and regulation of the signaling may be useful in therapeutic strategies to control scarring and/or fibrosis.

In addition to collagen production, fibroblasts can migrate to a certain degree, and this process is mediated by adhesion molecules that bind to the ECM. This binding is a complicated event in which the adherence process is essential for migration of the cell and also its anchoring to extracellular proteins. During wound repair, proliferating fibroblasts will often align themselves parallel with lines of tension stress.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 4.7.7 MORPHOLOGY OF GRANULATION TISSUE AND FIBROUS CONNECTIVE TISSUE

#### 4.7.7.1 GRANULATION TISSUE

Some lesions develop a distinctive type of arrangement of connective tissue fibers, fibroblasts, and blood vessels termed granulation tissue. Granulation tissue is the exposed connective tissue that forms within a healing wound. It is often red, is hemorrhagic, and bleeds easily when bumped or traumatized because of the fragility of the newly formed capillaries (Fig. 4-27). It is especially common in horses. When viewed with a magnifying glass, the surface of granulation tissue has a granular appearance and thus the term *granulation tissue* arose. In granulation tissue, fibroblasts and connective tissue fibers grow parallel to the wound surface and are arranged perpendicularly to the proliferating capillaries. Often the penetrating blood vessels are evenly spaced. Excessive granulation can lead to a type of hypertrophic scar called proud flesh.

##### 4.7.7.1.1 Hypertrophic Scars

Hypertrophic scars occur as a result of exuberant proliferation of fibroblasts and collagen in wounds that fail to heal properly. The best example of this condition occurs in skin wounds of the distal limbs of horses and is known as “proud flesh,” as indicated proliferating connective tissue forms a large cauliflower-like mass that cannot be covered by epithelium (Fig. 4-28). Why this lesion most commonly occurs in horses is unclear; however, the epidermis of horses is often very “tight” with limited elasticity.

183

184

Fig. 4-27 **Granulation tissue, nonhealing ulcer, skin, distal limb, horse.**

**A**, In the bed of the ulcer, there is extensive fibrosis and granulation tissue. **B**, Gross photograph of the surface of granulation tissue. Note the fine nodules or “granulations” on the surface that gave rise to the term *granulation tissue*. They are a mixture of newly formed blood vessels, extracellular matrix (ECM), and fibroblasts, with no to minimal collagen deposition. It provides the support for wound repair and remodeling via fibroplasia and reepithelization. **C**, Photomicrograph of granulation tissue. Note how the new fibroblasts are arranged perpendicularly to the newly formed blood vessels in a rich bed of ECM (*clear spaces*). Collagen deposition is sparse at this time. H&E stain. (**A**, **B**, and **C**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 4-28 Exuberant granulation tissue (proud flesh), chronic ulcer, skin, distal hindlimb, horse.** Note the large proliferating mass of fibrous tissue on the lower portion of the left hindlimb. It often lacks superficial epithelium. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

Keloid is a special type of excessive connective tissue deposit that occurs in human beings. It has an incidence of 5% to 16% following skin trauma in high-risk populations, such as blacks, Hispanics, and Asians. Clinical management of hypertrophic scars, proud flesh, and keloids can be difficult but includes intralesional corticosteroids, compression, occlusive dressings, pulsed-dye laser therapy, cryosurgery, surgical excision, radiation, fluorouracil chemotherapy, topical silicone, interferons, and drugs, such as imiquimod, that induce IFN- $\gamma$ .

### 4.7.7.2

#### FIBROUS CONNECTIVE TISSUE

Fibrous connective tissue is the dense accumulation of fibroblasts and collagen formed within a wound site. Histological characteristics depend on wound severity and duration. Fibrous connective tissue contains variable numbers of fibroblasts and collagen along with inflammatory cells (Fig. 4-29). In recently formed wounds, the collagen can be very immature and edematous with a variety of inflammatory cells, perhaps neutrophils. With time, the fibrous connective tissue progresses into mature, densely packed collagen with few inflammatory cells. Once formed and matured, fibrous connective tissue often persists for years, perhaps life.

184

185

Fig. 4-29 **Fibrous connective tissue.** **A**, Hemomelasma ilei, ileum, antimesenteric serosal surface, horse. This lesion is approximately 1 to 2 weeks old. *Strongylus edentatus*–induced injury to the serosal vasculature results in hemorrhage followed by wound healing. Note the raised areas of fibrosis (raised gray-white areas), hemosiderosis (yellow-brown areas), and hemorrhage (red-brown areas). **B**, Healing response in hemomelasma ilei. Note the abundant newly formed capillaries (*arrowheads*) and intervening fibrous connective tissue (bands of red fibers). This healing response is the next step following the granulation tissue phase demonstrated in Fig. 4-27. Hemosiderin (*arrows*) is present in the connective tissue and is indicative of hemorrhage having occurred in the injury at an earlier time (weeks). H&E stain. **C**, Fibrous connective tissue in the healing response. Collagen is readily demonstrated in fibrous connective tissue by a Trichrome stain (*blue stained fibers*). Masson trichrome stain. (**A**, **B**, and **C**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

### 4.7.8 WOUND CONTRACTION

#### 4.7.8.1 THE SCIRRHOUS REACTION

With severe thermal/chemical burns or extensive abrasions of a large surface area of the skin, the healing process and the formation of connective tissue becomes extensive. In time, these areas of connective tissue contract and place tension on the surrounding normal skin, resulting in a scirrhous reaction that can cause immobility of the surrounding skin and perhaps limbs along with pain and deformation. Contraction of such wounds is mediated largely by myofibroblasts.

Similarly, within areas of necrosis and/or inflammation in the liver, lung, spleen, and kidney, excessive fibrosis in parenchymal areas can result in the formation of connective tissue tracts between the healing area and capsular and interstitial connective tissue. When this new connective tissue contracts during the healing process, it grossly results in local indentation or pitting on the organ surface, such as occurs with chronic renal cortical infarcts. If there are multiple such areas, the organ surface develops an undulating and/or nodular appearance, such as occurs in a cirrhotic liver. Contraction of such wounds is again mediated largely by myofibroblasts.

##### 4.7.8.1.1 Myofibroblasts

Myofibroblasts are specialized fibroblasts with contractile activity. They form within wounds in response to tissue plane stress and the secretion of TGF- $\beta$  by platelets and macrophages as wounds develop, and they increase in number with time and severity. Their function is to contract the wound and thus bring together injured tissue separated by edema and inflammation. Physiologically, myofibroblasts also occur in tissues with contractility, such as uterine submucosa, intestinal villi, testicular stroma, the ovary, periodontal ligament, bone stroma, capillaries, and pericytes.

Myofibroblasts have stress fibers, actin and myosin fibers, gap junctions, and a fibronexus. The fibronexus is a mechanotransduction region of the plasma membrane, which is rich in integrin molecules. The fibronexus interconnects intracellular actin fibers with extracellular proteins, such as fibronectin. This provides an anchor point during myofibroblast contraction. In contrast, fibroblasts lack contractile myofilaments and a fibronexus. Actin polymerization and contractility in myofibroblasts is stimulated by Rho GTPases. The Rho signaling that induces contractility in myofibroblasts results in continual contraction of filaments in myofibroblasts. Such contractions condense wound sites. This type of contraction by myofibroblasts differs from the periodic contractility that occurs in smooth muscle cells.

185

186

Fig. 4-30 **Steps in the process of angiogenesis.** *ECM*, Extracellular matrix.  
(Modified from Motamed K, Sage EH: *Kidney Int* 51:1383, 1997.)

### 4.7.9 ANGIOGENESIS IN WOUND REPAIR

Angiogenesis in simple terms is the formation of new blood vessels. It is a process essential for all living organisms with a cardiovascular system and involves a series of steps, as illustrated in Fig. 4-30, for the formation of new capillaries, including the following:

- Proteolysis of the ECM and basement membrane of parental vessels at the margins of the wound so a new capillary “bud” can form and initiate cellular migration
- Migration of immature endothelial cells into the wound
- Proliferation of endothelial cells to form solid “endothelial tubes”
- Maturation of endothelial tubes into new capillaries with the formation of lumina
- Establishment of inter-endothelial gap junctions and the receptors/ligands responsible for the leukocyte adhesion cascade along the luminal surface of the endothelial cells
- Recruitment of pericytes and smooth muscle cells to support the final differentiation stage of the newly formed vessel

This process occurs because as wounds heal, new vessels are necessary to supply the injured site with oxygen, remove carbon dioxide and other waste products, drain excess fluid, and provide a vascular pathway for cells and stem cells into the wound. This same beneficial process has also been adapted by primary and metastatic neoplastic cells to grow and spread throughout tissues of the body.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 4.7.9.1 INITIATION OF ENDOTHELIAL CELL PROLIFERATION

#### 4.7.9.1.1 Endothelial Cell Growth Factors

The formation of new blood vessels in wounds begins from the proliferation of endothelial cell buds from blood vessels in viable tissue adjacent to the wound or can be derived from bone marrow endothelial precursor cells (EPCs) (Fig. 4-31). These buds grow into the “healing” wound, form elongated vascular tubular structures within the wound, interconnect and revascularize the wound, and then eventually differentiate into mature vessels. Initially, endothelial cell buds form, and cells migrate into wounds under the autocrine (see Fig. 12-1) influence of HIF- $\alpha$  and EGF (see Expression of Genes Responsible for Wound Repair), which enhance expression of genes that improve cell survival in hypoxic conditions.

Concurrently, growth factors such as FGF, VEGF A, angiogenins, and ephrins released from macrophages, endothelial cells, and fibroblasts bind receptors on endothelial cells and induce their proliferation (Fig. 4-32). VEGF A stimulates the initial stages of endothelial cell proliferation through binding the VEGF R2 receptor on endothelial cells. The secondary stages of endothelial cell proliferation appear to involve angiopoietin 1 and its receptor, Tie2.

186

187

**Fig. 4-31 Angiogenesis by mobilization of endothelial precursor cells (EPCs).** **A**, Bone marrow. EPCs are mobilized from the bone marrow and may migrate to a site of injury. The homing mechanisms have not yet been defined. At these sites, EPCs differentiate and form a mature network by linking with existing vessels. **B**, Preexisting vessels (capillary growth). In angiogenesis from preexisting vessels, endothelial cells from these vessels become motile and proliferate to form capillary sprouts. Regardless of the initiating mechanism, vessel maturation (stabilization) involves the recruitment of pericytes and smooth muscle cells to form the periendothelial layer. (**A and B**, Modified from Conway EM, Collen D, Carmeliet P: *Cardiovasc Res* 49:507, 2001.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

4.7.9.1.2

### Endothelial Cell Migration is Mediated by Integrins

Newly formed endothelial cells and fibroblasts migrate into wound sites and bind to fibrinogen and plasma proteins as well as newly deposited ECM substances, such as heparan sulfate, chondroitin sulfate, type III collagen, laminin, vitronectin, and fibronectin. This adherence is mediated by adhesion molecules expressed by new endothelial cells and fibroblasts. These adhesion molecules include  $\alpha_5$ - and  $\beta_3$ -integrins, which bind fibrin and fibronectin (Fig. 4-32). It is interesting that for wound repair, enhancement of angiogenesis is beneficial and vital; however, in neoplasia, inhibition of angiogenesis and thus the growth of the tumor has potential therapeutic benefits.

4.7.9.1.3

### Vascular Remodeling

Once blood vessels are initially formed, they are loosely arranged and require remodeling to become mature. With remodeling, endothelial cells produce a mature basement membrane. In addition, smooth muscle cells and pericytes can form within the wall, and fibroblasts can form adventitial fibers, depending on whether the vessel is a capillary, artery, vein, or lymphatic vessel. Other endothelial cell growth factors and receptors involved with vascular remodeling include angiopoietin 2, which also binds Tie2 and ephrin B2 and its receptor, EphB4. Proliferation of lymphatic endothelial cells is mediated largely by VEGF C and its receptor, VEGF R3, as well as prox 1 gene expression.

4.7.9.1.4

### Regulators/Inhibitors of Endothelial Cell Growth

Inhibitors of angiogenesis are produced by endothelial cells, macrophages, and fibroblasts. These inhibitors balance the proliferative healing responses of angiogenesis and to prevent overexuberant proliferation of endothelial cells. These inhibitors include angiostatin, endostatin, thrombospondin, and specialized CXC chemokines (lacking ELR motif). Such inhibitors of angiogenesis are being studied intensely for their potential chemotherapeutic role against certain types of cancer.

187

188

Fig. 4-32 **Molecular mediators of angiogenesis.** Growth factors, such as vascular endothelial growth factor A (VEGF A) and angiopoietin-1 (ANG-1), bind receptors on endothelial cells that induce proliferation and migration. The migration is mediated by  $\alpha_5\beta_3$ -integrins expressed by endothelial cells that bind molecules, such as fibrin and fibronectin. Factors such as Ephrin B2 bind endothelial receptors Ephrin B4 and mediate vascular remodeling. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

### 4.7.10 EPITHELIALIZATION IN WOUND REPAIR

Epithelialization (reepithelialization) is the process by which the skin and mucous membranes replace superficial epithelial cells damaged or lost in a wound. Epithelial cells at the edge of a wound proliferate almost immediately following injury to cover the denuded area. Under normal conditions, this process is rapid, and first intention healing occurs in 3 to 5 days to repair the wound. During wound repair, keratinocytes and mucosal epithelial cells must move laterally across the wound surface to fill the void. Before this lateral movement can occur, epithelial cells must disassemble their connections to the underlying basement membrane and their junctional complexes with neighboring cells. They must also express surface receptors that permit movement over the ECM of the wound surface.

#### 4.7.10.1 INTACT BASEMENT MEMBRANES ENHANCE REEPITHELIZATION

The presence or rapid deposition of basement membrane into the wound greatly facilitates proliferation of viable epithelial cells at the margins of the wound. For example, with initial loss of enterocytes that cover the

## Pathologic Basis of Veterinary Disease, 4th Edition

surface of intestinal villi or renal tubular cells that line proximal convoluted tubules, the immediate response is for the adjacent normal epithelial cells to extend over the denuded basement membrane and to cover the area, if it is larger, by becoming thin, elongated cells. At the same time, there is proliferation (mitosis) of viable adjacent epithelial cells, and these cells migrate along the basement membrane to cover the denuded surface and replace lost cells. Without a basement membrane, proliferative cells lack a clear path of migration. The immature cells may loiter at the site of proliferation and fuse, thus forming syncytial cells, as can be seen with renal tubular injury and the failure of the tubular epithelium to migrate.

Similarly, regenerating skeletal muscle cells and transected axons will regenerate inside a tube surrounded by 188

basal lamina and endoneurium. Components of the basement membrane, including laminin, type III collagen, and the associated proteoglycans, provide a substratum for epithelial and other cells to bind the basement membrane via integrins, proliferate, and migrate along the basement membrane surface. 189

### 4.7.10.2 INITIATION OF CELL PROLIFERATION IN EPITHELIA

Growth factors are vital for the proliferation of keratinocytes, mucosal epithelia, renal tubular cells, and other parenchymal epithelial cells. In skin and other surface epithelia, for example, keratinocyte growth factor (KGF) and EGF bind receptors on epithelial cells and induce signal transduction, which activates mitogen-activated protein kinases (MAPKs) that induce cells in the nonproliferating  $G_0$  phase of the cell cycle to enter the cycle and proliferate (see [Chapter 6](#)). Hepatocyte growth factor (HGF) induces proliferation of hepatocytes, and nerve growth factor (NGF) enhances growth of nerve fibers. Cell proliferation is regulated by: (1) the amount of growth factor produced, (2) the level of expression of the growth factor receptor, (3) inhibitory signals from other growth factors, (4) the microenvironment including the availability of oxygen and nutrients, and (5) integrin attachment to an established basement membrane. Although TGF- $\beta$  induces fibroblast proliferation and collagen deposition, TGF- $\beta$  inhibits proliferation of epithelial cells in many parenchymal organs.

### 4.7.10.3 DIFFERENTIATION OF EPITHELIA

Once epithelial cells have filled in a gap in the epithelium of a tissue or an organ, cellular differentiation is required for return of the tissue or organ to normal function. FGF 10 is a key initiator of wound repair in skin and lung epithelia ([Fig. 4-33](#)). FGF 10 binds FGF R III, which through bone morphogenic protein 4 and sonic hedgehog (a signaling protein for developmental patterning) enhances expression of several transcription factors, including GATA-6, thyroid transcription factor-1 (TTF-1), hepatocyte nuclear factor- $\beta$  (HNF- $\beta$ ), and hepatocyte factor homolog-4 (HFH-4). Each of these transcription factors enhance expression of genes, which regulate a specific function for a particular cell. In the lung, for example, TTF-1 induces production of surfactant proteins A, B, and C, and HFH-4 stimulates cilia formation. Activity of these transcription factors is reduced in the presence of NF kappa B, an important mediator of inflammation. Therefore concurrent inflammation can impair differentiation of epithelial and parenchymal cells and thus inhibit or delay reepithelization.

## Pathologic Basis of Veterinary Disease, 4th Edition

Fig. 4-33 **Epithelial cell differentiation, growth, and transcription factors.**

Fibroblast growth factor 10 (*FGF-10*) binds epithelial receptor fibroblast growth factor receptor IIIB (*FGF R IIIB*), which activates bone morphogenic protein and sonic hedgehog that induce activity of transcription factors for epithelial cell differentiation. This process is inhibited with inflammatory conditions that have increased levels of nuclear factor (*NF*) kappa B. *HFH-4*, Hepatocyte factor homolog-4; *HNF-β*, hepatocyte nuclear factor-β; *TTF-1*, thyroid transcription factor-1. (Redrawn with permission from Dr. M.R. Ackermann, College of Veterinary Medicine, Iowa State University.)

### 4.7.10.4 METAPLASIA IN WOUND REPAIR

Some wounds do not heal properly and can turn into hypertrophic scars that impair epithelial and parenchymal cell growth. Such wounds may remain ulcerated or in parenchymal organs; the injured site may be replaced by fibroblasts and inflammatory cells rather than parenchymal cells. In either case, epithelial and parenchymal stem cells may continually attempt to cover or fill wound defects. With time, these cells may convert to another cell or tissue type. For example, regions of the lung constantly exposed to smoke can change from pseudostratified epithelium to stratified squamous epithelium, or regions of lower esophagus continually exposed to gastric acidity can undergo metaplasia into squamous cells. Osseous and chondroid metaplasia can occur in persistent wounds. In general, cells that undergo metaplasia have either: (1) enhanced expression of an altered set of transcription factors and/or (2) decreased expression of transcription factors generally active for the affected tissue. The result is conversion of the cell's phenotype into a new phenotype. Often, if the initiating stimulus is removed, cells can revert to the original phenotype.

VLA-4	Very late antigen-4	Leukocyte adhesion

## 5 Chapter 5 Diseases of Immunity

PAUL W. SNYDER

### 5.1 GENERAL FEATURES OF THE IMMUNE SYSTEM

The immune system is a defensive system whose primary functions are to protect against infectious organisms such as bacteria, viruses, fungi, and parasites and the development of cancer. The complexity by which these functions occur is evidenced not only by the cell types, recognition molecules, and soluble factors involved and interactions with other systems (e.g., endocrine, nervous), but also by the ability to recognize virtually any foreign antigen. Immunologic responses result in pathologic processes, primarily inflammatory responses, as a result of either normal immune responses to foreign antigens (e.g., microbial pathogens) or from aberrations of the immune system as in the case of hypersensitivity reactions and autoimmune diseases. Finally, the importance of a normal functional immune system cannot be more evident than in instances when it is deficient as the result of a genetic defect or as the result of an acquired immunodeficiency disease.

Immunity is the result of nonspecific (innate) and specific (adaptive) responses that together provide effective protection. The immune system's recognition and response functional capabilities are key components of both innate and adaptive immune responses. The recognition capabilities are highly specific and allow immune responses to develop against a diverse group of foreign (nonself) antigens and prevent the development of immune responses to self-antigens. Innate and adaptive immune responses feature effector mechanisms for eliminating or neutralizing the antigen, whereas adaptive immunity has the additional feature of memory. The emphasis of this chapter is on diseases that are the result of inadequate or inappropriate immune responses. Before one can understand the pathogenic mechanisms of these diseases, one must first have an understanding of the basic elements of the immune system. The chapter begins with an overview of our current understanding of innate and adaptive immunity, cells of the immune system, cytokines, and major histocompatibility complex (MHC) molecules. This overview will facilitate our discussion of disorders of the immune system that will include hypersensitivity reactions, autoimmunity, and immunodeficiency. This chapter concludes with a discussion of amyloidosis, a diverse group of conditions characterized by the deposition of a pathologic extracellular protein. One of the conditions is associated with the deposition of immunoglobulin components. Although the focus of this text is on the pathologic basis of veterinary diseases, with an emphasis on domestic species, in this chapter we use the vast knowledge base regarding human and rodent immunology (applicable to most mammalian species studied to date) as our basis and interject major known relevant species differences as appropriate.

### 5.2 INNATE IMMUNITY (NONSPECIFIC IMMUNITY)

As stated previously, the function of the immune system is to protect against infectious pathogens and the development of cancer. There are two categories of immune responses that are based in part on their specificity for the antigen: (1) innate immunity and (2) adaptive immunity (Fig. 5-1). Innate immune responses are considered the first-line defense mechanisms, are not specific to the antigen, and lack memory. These defense mechanisms are the result of anatomic (e.g., skin, mucosal epithelia, cilia) and physiologic (stomach pH, body temperature, etc.) properties, and phagocytic and inflammatory responses. Major components of innate immunity are intact epithelial barriers, phagocytic cells, natural killer (NK) cells, and a number of plasma proteins, the most important of which are the proteins of the complement system. Phagocytic cells are recruited to sites of infection during an inflammatory response where they have a number of functions, two of which are to ingest and destroy pathogenic organisms and neutralize toxins. Neutrophils, monocytes, and tissue macrophages are the major cells involved in phagocytosis. These cells recognize components of microbial pathogens through the expression of several

193

194

## Pathologic Basis of Veterinary Disease, 4th Edition

membrane receptors, including receptors for mannose residues and *N*-formyl-methionine containing peptides and a newly discovered family of Toll-like receptors (TLRs) that are homologues of the Toll receptor. TLRs are a family of pattern recognition receptors that, when activated by microbial components, signal the activation of transcription factors that facilitate the microbicidal mechanisms of the phagocytic cell. NK cells are the cytotoxic cells of innate immunity and are discussed later. The complement system, discussed in [Chapter 3](#), is a complex cascade of proteins that has a number of biologic functions, including the formation of the membrane attack complex that efficiently lyses plasma membranes of microbial pathogens. The complement system can be activated by either the innate immune system (alternative and mannose/lectin pathways) or the adaptive immune system (classical pathway). Other important plasma proteins of the innate immune system include mannose-binding protein and C-reactive protein; two of the functions of these proteins are to facilitate phagocytosis through opsonization of pathogens and complement activation. Inflammatory responses comprise vascular, permeability, and cellular phases that act in response to damage to vascularized tissue. The features of the inflammatory response are also presented in [Chapter 3](#).

Fig. 5-1 Innate (nonspecific) and adaptive (specific) immunity are depicted in relation to the time course of an infection. *NK*, Natural killer. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 5.2.1 TOLL-LIKE RECEPTORS

TLRs are the mammalian homologue of the Toll receptor originally identified in *Drosophila*. It has not only an embryologic function but also an immunologic function. In mammals, TLRs are membrane molecules that function in cellular activation by a wide range of microbial pathogens. TLRs are classified as pattern recognition receptors (PRRs) because they recognize pathogen associated molecular patterns (PAMPs) and signal to the host the presence of an infection. Pathogen associated molecules include lipopolysaccharide (LPS)

194

195

## Pathologic Basis of Veterinary Disease, 4th Edition

from gram-negative bacteria, peptidoglycan from gram-positive bacteria, double-stranded RNA from viruses, or  $\alpha$ -glucans from fungi (Table 5-1). In general, TLRs 1, 2, 4, and 6 recognize unique bacterial products that are found on the cell surface, and TLRs 3, 7, 8, and 9 are involved in viral detection and nucleic acid recognition within endosomes. The specificity of TLRs for microbial products is dependent on interactions between TLRs and non-TLR adapter molecules. All TLRs contain an extracellular domain characterized by a leucine-rich repeat motif flanked by a cysteine-rich motif (Fig. 5-2). They also contain a conserved intracellular signaling domain, Toll/interleukin (IL)-1 receptor (TIR), that is identical to the cytoplasmic domain of the IL-1 and IL-18 receptors. Fig. 5-2 illustrates how TLRs function in the recognition of LPS. In the blood or extracellular fluid, the binding of LPS to LPS binding protein (LBP) facilitates the binding of LPS to CD14, a plasma protein and glycosphosphatidylinositol-linked membrane protein present on most cells. The binding of LPS to CD14 results in the dissociation of LBP and the association of the LPS-CD14 complex with TLR4. An accessory protein, MD2, complexes with the LPS-CD14-TLR4 molecule and results in LPS-induced cell signaling.

Table 5-1 Toll-like Receptors (TLRs) and TLR Ligands and Their Microbial Source

TLR	Ligand	Microbial Source
TLR2	Lipoproteins	Bacteria
	Peptidoglycan	Gram-positive bacteria
	Zymosan	Fungi
	LPS	<i>Leptospira</i>
	GPI anchor	Trypanosomes
	Lipoarabinomannan	Mycobacteria
	Phosphatidylinositol dimannoside	Mycobacteria
TLR3	Double-stranded RNA	Viruses
TLR4	LPS	Gram-negative bacteria
	HSP60	Chlamydia
TLR5	Flagellin	Various bacteria
TLR6	CpG DNA	Bacteria, protozoans
TLR7	Single-stranded RNA	Viruses
TLR8	Single-stranded RNA	Viruses
TLR9	CpG DNA	Bacteria, viruses

Briefly, TLR signaling through the binding of PAMP to a TLR leads to the activation of TIR, which forms a complex with the cytoplasmic adapter protein MyD88, an IL-1 receptor associated kinase (IRAK), and tumor necrosis factor receptor-associated factor 6 (TRAF6). Activated TRAF then activates the mitogen-activated protein kinase (MAPK) cascade leading to the activation of nuclear factor (NF) kappa B, a transcription factor. MyD88 is a universal signaling molecule for NF kappa B activation, and MyD88 deficient mice are incapable of activation by TLR, IL-1 and IL-18. Recent information suggests that there are also signaling mechanisms unique to individual TLRs.

**Fig. 5-2 Signaling pathway for Toll-like receptor 4 (TLR4) in response to bacterial lipopolysaccharide (LPS).** The binding of LPS to TLR4 results in activation of a signal transduction pathway, leading to gene transcription and the elicitation of an inflammatory response. *AP-1*, Activating protein 1; *NF-κB*, nuclear factor kappa B; *TIR*, Toll/interleukin-1 receptor. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

TLRs and their pathogen-associated ligands are important recognition molecules for the innate immune system and trigger a number of antimicrobial and inflammatory responses. Up to 15 different TLR genes have been identified. The importance of these receptors in immunity is further supported by the observation of polymorphisms in the genes encoding them.

Although the individual TLRs exhibit ligand specificity, they differ in their cellular expression patterns and the signal pathways they activate, similar to that described for cytokines, which exhibit pleiotropy, redundancy, synergy, and antagonism. There are constitutively and inducibly expressed TLRs in different tissues. TLRs regulate cell recruitment to sites of infection through the up-regulation of the expression of adhesion molecules, chemokines, and chemokine receptors during an inflammatory response. TLRs activate leukocytes (primarily neutrophils and NK cells of the innate immune system) and epithelial, endothelial, and hematopoietic cells. TLRs are also hypothesized to be essential for linking the innate immune response to the adaptive immune responses. Central to this hypothesis is the TLR-dependent dendritic cell-mediated control of T lymphocyte activation. Dendritic cells are important antigen-presenting cells for T lymphocyte activation. Dendritic cells uptake microbial antigens in the peripheral tissues and migrate to regional lymph nodes where they present peptide fragments, in the context of MHC molecules, to naïve T lymphocytes. In addition to the expression of the peptide-MHC signal, dendritic cells are also required to provide a second, co-stimulatory signal through the expression of B7, the ligand for the CD28 molecule on naïve T lymphocytes. The activation and maturation pathway related to the co-stimulatory signal occurs through TLR recognition of PAMPs.

There are species differences in the ligand specificity of TLRs and in the cellular responses elicited. Although sequences for canine, feline, and chicken TLR4 have been identified, no functional data have been published. With regard to domestic animals, a significant body of literature exists on TLRs of cattle.

Finally, TLRs have been implicated in “innate autoimmunity,” with several reports of TLRs recognizing fibrinogen, heat-shock proteins, or DNA. There are also reports of TLR binding of DNA as a factor in directing antibody production by autoreactive B lymphocytes contributing to the pathogenesis of rheumatoid arthritis and systemic lupus erythematosus. Further studies are necessary to more fully understand these observations and the underlying immunopathogenesis.

### 5.3 ADAPTIVE IMMUNITY (SPECIFIC IMMUNITY)

Adaptive immunity in general consists of cell-mediated immunity, mediated by T lymphocytes against intracellular pathogens, and humoral immunity, mediated by B lymphocytes against extracellular pathogens and toxins (Fig. 5-3). The adaptive immune response is the second-line defense mechanism and is characterized by antigen specificity, diversity, memory, and self/nonself recognition. Antigen specificity and self/nonself recognition are the result of distinct membrane molecules. Mature B lymphocytes are activated by a specific antigen-binding molecule on its membrane. The antigen receptor is membrane-bound immunoglobulin. Mature T lymphocytes express a specific antigen-binding molecule, the T-cell receptor (TCR), on their membrane. Unlike membrane-bound immunoglobulin on the B lymphocyte, which can recognize antigen alone, TCRs can recognize only antigens that are associated with cell membrane proteins called major histocompatibility complex (MHC) molecules. Self/nonself recognition is the result of MHC molecules. There are two major classes of MHC molecules. Class I molecules are present on all nucleated cells, and class II molecules are present primarily on antigen-presenting cells. T lymphocytes and B lymphocytes are the major cells of adaptive immunity.

#### 5.3.1 CELLS AND TISSUES OF THE IMMUNE SYSTEM

##### 5.3.1.1 T LYMPHOCYTES

T lymphocytes are small nongranular cells that constitute 50% to 70% of the peripheral blood mononuclear cells. They originate in the bone marrow and migrate to the thymus (thus the “T” designation), where they undergo differentiation, selection, and maturation processes before exiting to the periphery as effector cells.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In secondary lymphoid tissues, they are located primarily in the paracortical regions of lymph nodes and the periarteriolar sheaths (PALS) of the spleen. These specific anatomic sites elaborate chemoattractant cytokines (chemokines), for which the T lymphocytes express receptors. The definitive marker for T lymphocytes is the TCR, the polymorphic antigen-binding molecule. The antigen specificity of individual lymphocytes is attributed to their respective TCR, which is genetically determined. TCRs are classified as either  $\alpha\beta$ -TCR or  $\gamma\delta$ -TCR based on the composition of their disulfide-linked heterodimers. The individual polypeptide chains of the heterodimers contain variable (antigen-binding) and constant regions. In mammals, most peripheral blood T lymphocytes express  $\alpha\beta$ -TCR; however, in ruminants and swine these cells make up only 10% to 50%, and 10% of peripheral blood T lymphocytes, respectively. Both TCRs are associated with CD3, and together they form the TCR-CD3 complex. There are significant activation and functional differences between  $\alpha\beta$ -TCR- and  $\gamma\delta$ -TCR-expressing lymphocytes. Unlike membrane bound immunoglobulin on B lymphocytes that can recognize soluble antigen, the  $\alpha\beta$ -TCR can only recognize antigen after it has been processed into peptide fragments and associated with MHC molecules (the MHC is discussed later). In most instances the antigen is associated with the MHC on the surface of an antigen-presenting cell, a virally infected cell, a neoplastic cell, or a cell of a foreign tissue graft. Individual  $\alpha\beta$ -TCRs are covalently linked to a cluster of five polypeptide chains, three comprising the CD3 molecule and two comprising the  $\beta$ -chain. The CD3 molecule and the  $\beta$ -chain are invariant, and although they do not bind antigen, they do function in the signal transduction following antigen binding by the TCR. Each T lymphocyte expresses a unique TCR with regard to structure and antigen specificity. The genes that encode  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains of the TCR can undergo somatic rearrangements during their development in the thymus, resulting in tremendous diversity for antigen recognition. Not only are these rearrangements important for diversity, they can also be used to molecularly phenotype proliferating populations of T lymphocytes as a diagnostic tool for the identification of clonal populations (neoplastic) and polyclonal populations (nonneoplastic)(see [Chapter 6](#)).

198

**Fig. 5-3 Overview of humoral and cell-mediated arms of adaptive immunity.** CTL, Cytotoxic T lymphocyte. (Adapted from Goldsby RA, Kindt TJ, Osborne BA: *Kuby immunology*, ed 4, New York, 2000, WH Freeman.)

In most species a minority of T lymphocytes express  $\gamma\delta$ -TCR. The  $\gamma\delta$ -TCR lymphocytes develop in the thymus and migrate to the epithelium of the skin and intestine, mammary gland, and reproductive organs. Although these cells can be found with in regional lymph nodes and the lamina propria, in these organs they primarily reside as intraepithelial lymphocytes (IELs). As stated already, in some species, notably ruminants,  $\gamma\delta$ -TCR lymphocytes are the predominant circulating population of T lymphocytes. In contrast to the  $\alpha\beta$ -TCR lymphocytes,  $\gamma\delta$ -TCR lymphocytes can recognize native antigen in the absence of MHC binding and they do not rely exclusively on the  $\delta$ -chain as a signal transducer. Most  $\gamma\delta$ -TCR lymphocytes use the  $\gamma$ -chain for signal transduction following activation. The diversity of antigens recognized by  $\gamma\delta$ -TCR is limited in most species except ruminants and swine, indicating their importance in these species. Some have suggested that they may provide early cell-mediated immune responses in neonates. The precise function of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

$\gamma\delta$ -TCR lymphocytes remains unknown. Another small subset of T lymphocytes, called NK-T lymphocytes, expresses molecules found on NK cells in addition to a limited diversity of TCRs. NK-T lymphocytes primarily recognize glycolipids that are associated with an MHC-like molecule, CD1. The function of NK-T lymphocytes remains unknown.

Although all T lymphocytes express the TCR-CD3 complex, they are further classified according to accessory CD4 and CD8 molecules. These nonpolymorphic accessory molecules include CD4, CD8, CD2, integrins, and CD28. CD4 and CD8 functionally subdivide T lymphocytes into CD8<sup>+</sup> cytotoxic T lymphocytes (T<sub>C</sub>) and CD4<sup>+</sup> helper T lymphocytes (T<sub>H</sub>). During antigen presentation, CD4<sup>+</sup> lymphocytes only recognize antigen bound to MHC class II molecules (Fig. 5-4), whereas CD8<sup>+</sup> lymphocytes only recognize antigen bound to MHC class I molecules. This co-receptor requirement is commonly referred to as MHC class I and MHC class II restriction, the basis for positive selection in the thymus. Although there have been reports in some species of CD4 cells that are functionally cytotoxic and CD8 cells that are functionally “helper”-like, these appear to be anomalies and for the purposes of this text are excluded. In most species, peripheral blood T lymphocytes express either CD4 or CD8. Except for ruminants and swine, cells negative for both CD4 and CD8—“double negative” lymphocytes—are rare in the peripheral blood. So-called double lymphocytes cells positive for both CD4 and CD8, positive are rare except in swine, where they can approach 25% of the T lymphocytes in the peripheral circulation. T lymphocytes require two signals for activation. Signal 1 is provided by the TCR and the MHC-antigen complex, and the CD4 or CD8 MHC complex. Signal 2 is provided by another accessory molecule expressed by T lymphocytes, the CD28 molecule. The ligands for CD28 are B7-1 (CD80) and B7-2 (CD81) expressed on activated dendritic cells, B lymphocytes and macrophages (Fig. 5-4). An inability to deliver the second signal results in an unresponsive T lymphocyte that either undergoes apoptosis or remains anergic. These molecules provide an important co-stimulatory signal for T lymphocyte activation, and are discussed in more detail later in the chapter regarding anergy and the development of tolerance with regard to autoimmunity. When T lymphocytes are activated by antigen and receive the appropriate co-stimulatory signals, they clonally expand as a result of their secretion of IL-2. This clonally expanded population of T lymphocytes, of the same antigen specificity, differentiates into populations of effector cells and memory cells.

## Pathologic Basis of Veterinary Disease, 4th Edition

$T_H$  lymphocytes can be classified based on their functional capacity and ability to elicit primarily an antibody response or a cell-mediated immune response. Following activation of  $T_H$  lymphocytes, by recognition of antigen bound to MHC class II molecules on the surface of an antigen-presenting cell, there is clonal expansion of  $T_H$  lymphocytes of the same antigen specificity. These clonally expanded cells are important in directing the immune response as either primarily an antibody response or a cellular response. The type of response is dictated by a restricted cytokine profile that primarily activates B lymphocytes in the case of an antibody response or activates  $T_C$  lymphocytes and macrophages in a cellular response. The restricted cytokine profile for  $T_H$  lymphocytes allows for their classification as either  $T_H1$  or  $T_H2$  lymphocytes (Table 5-2).  $T_H1$  lymphocytes synthesize and secrete IL-2 and interferon- $\gamma$  (IFN- $\gamma$ ), stimulating  $T_C$  lymphocytes and macrophages, and induce a cell-mediated immune response.  $T_H2$  lymphocytes synthesize and secrete IL-4, IL-5, IL-6, and IL-13 that stimulate B lymphocytes to develop into antibody-secreting plasma cells and inhibit macrophage functions, and induce an antibody response. The type of immune response (antibody versus cell-mediated) can have a profound influence on the outcome of a disease. In the instance of an intracellular protozoal infection, a  $T_H2$  type response results in rapid proliferation of the organism and death of the host, whereas a  $T_H1$  type response results in elimination of the organism and survival of the host. Similarly, a  $T_H2$  response to an allergen results in the elaboration of immunoglobulin (Ig)E, through IL-4 production, stimulation of eosinophils, through IL-5 production, and the development of an allergic reaction. The exact regulation of the  $T_H1$  versus the  $T_H2$  lymphocyte response is unknown, but studies suggest that IL-12 produced by activated macrophages stimulates the  $T_H1$  response, whereas IL-4 inhibits the  $T_H1$  response, allowing the  $T_H2$  response to dominate. Again, one must recognize that this is an oversimplification of a complex regulatory mechanism, and that as additional knowledge is gained about  $T_H1$  and  $T_H2$  responses, we will be able to understand pathogenic mechanisms of diseases, which will lead to the development of more specific therapeutic targets.

Table 5-2 Basic Cytokine and Functional Profiles of  $T_H1$  and  $T_H2$  Lymphocytes

### B LYMPHOCYTES

B lymphocytes constitute 5% to 20% of the peripheral blood mononuclear cells. B-lymphocyte development occurs in two phases, an antigen-independent phase in the primary lymphoid tissues, followed by an antigen-dependent phase in secondary lymphoid tissues. B lymphocytes can be found in primary lymphoid tissues like the bone marrow and ileal Peyer's patches (a primary lymphoid tissue in some species because it is the site of B-lymphocyte development, rather than the bone marrow), and in secondary lymphoid tissues like the spleen, lymph nodes, tonsils, and Peyer's patches. Within secondary lymphoid tissues B lymphocytes are aggregated in the form of distinct lymphoid follicles, which upon activation expand to form prominent pale regions called germinal centers ([Fig. 5-5](#)). This anatomic localization, similar to T lymphocytes in the PALS and paracortex, is the result of elaboration of chemokines for which the B lymphocyte has receptors. The antigen receptor of the B lymphocyte is the membrane bound immunoglobulin. Following the antigen-independent phase of development B lymphocytes express IgM and IgD on their surface that signifies a mature B lymphocyte. In the antigen-dependent phase, antigen-activated mature B lymphocytes differentiate into IgM-secreting plasma cells or switch to another antibody isotype. Immunoglobulins can be generated against an almost unlimited number of antigenic determinants through the rearrangement of genes encoding the light chain and heavy chain components. As in the case of the TCR, an evaluation of the rearranged genes of a B lymphocyte can be used to molecularly phenotype B lymphocyte neoplasms (see [Chapter 6](#)).

199

Like the T lymphocyte, the B lymphocyte also has accessory molecules that function to form the antigen receptor complex (Fig. 5-6). These nonpolymorphic molecules are nonpolymorphic heterodimers composed of Ig- $\alpha$  (CD79a) and Ig- $\beta$  (CD79b) that do not bind antigen but do interact with the transmembrane portion

## Pathologic Basis of Veterinary Disease, 4th Edition

of surface immunoglobulin involved in cell activation. B lymphocytes, unlike T lymphocytes, can recognize soluble antigens. Additional nonpolymorphic molecules that are important to B-lymphocyte functions are CD21 and CD40. The CD21 molecule is the complement receptor-2 molecule whose ligands are C3b and C3d. B lymphocyte responses to protein antigens are dependent on cytokines produced by activated T lymphocytes ( $CD4^{+}$ ). The CD40 molecule interacts with CD40 ligand on the surface of  $T_H$  lymphocytes and functions to allow B-lymphocyte development into antibody-secreting plasma cells. A failure to express CD40 ligand has been associated with an inability to isotype switch, resulting in a hyper-IgM syndrome. B lymphocytes activated by antigen develop into antibody secreting plasma cells and memory cells of the same antigenic specificity.

### 5.3.1.3

#### MACROPHAGES

Mononuclear phagocytic cells include circulating monocytes and tissue-based macrophages. In the spleen, macrophages are located in the marginal zone, white pulp, and red pulp, where they function primarily as phagocytic cells. In the lymph node, macrophages are located in the subcapsular sinus, which is analogous to the marginal zone of the spleen, and the medulla. These physical locations, the subcapsular sinus of lymph nodes and marginal zone of the spleen, facilitate their exposure to potential antigens. Nonlymphoid tissue-based macrophages have different functions and are named according to the tissue in which they reside (Table 5-3). One primary function of these cells is phagocytosis, as discussed in Chapter 3 regarding inflammation. Macrophages express Fc receptors for antibody and can phagocytose antigens opsonized by antibody or complement components. Another primary function is their involvement in the immune response as antigen-presenting cells. In this instance they phagocytose antigen, process it into peptide fragments which are then presented to T lymphocytes and the induction of cell-mediated immune responses. Although all nucleated cells express MHC class I molecules and could be considered antigen-presenting cells, only three cell types normally express MHC class II molecules and are regarded as the major antigen-presenting cells. They are the macrophage, dendritic cell, and B lymphocyte. Whereas B lymphocytes and dendritic cells constitutively express MHC class II molecules, macrophages express MHC class molecules upon activation.

200

201

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-3 Nomenclature and Location of Nonlymphoid Monocyte-Macrophage Cell Types

Organ/Tissue	Name	Location
Lung	Alveolar macrophages	Alveolar spaces
	Pulmonary intravascular macrophages	Capillaries of the lung
Connective tissues	Histiocytes	Interstitium
Kidney	Mesangial cells	Glomerular tuft
Brain	Microglial cells	Neuroparenchyma and perivascular areas
Bone	Osteoclasts	Bone marrow
Blood	Monocytes	Circulation
Liver	Kupffer cells	Hepatic sinusoids

Macrophages also have an important role in generation of a cell-mediated immune response, and are essential to type IV hypersensitivity reactions. Activated  $T_H1$  lymphocytes synthesize IFN- $\gamma$ , a potent activator of macrophages. Under the influence of IFN- $\gamma$ , macrophages have increased phagocytic activity and are more efficient at killing.

### 5.3.1.4

#### DENDRITIC CELLS

Dendritic cells comprise a distinct population of cells that are characterized by elongate cell processes. Most dendritic cells are antigen-presenting cells, which process antigens and present fragments to T lymphocytes. They are more efficient than macrophages and B lymphocytes at antigen presentation. Antigen-presenting dendritic cells are nonphagocytic, bone marrow-derived cells. They are the most important antigen-presenting cell for initiating primary immune responses to protein antigens (Fig. 5-7).

Antigen-presenting dendritic cells express a number of molecules, such as TLRs and mannose receptors, that make them efficient at capturing and responding to antigens. They also express high concentrations of MHC class II molecules and B7 co-stimulatory molecules. By expressing chemokine receptors similar to T lymphocytes, they have the ability to localize in T lymphocyte regions of lymphoid tissue. By colocalizing to these areas, they are uniquely positioned to present antigens to recirculating T lymphocytes.

Antigen-presenting dendritic cells function to capture antigen and then migrate to T lymphocyte areas of secondary lymphoid organs where they present fragments of the antigen on their surface and increase their expression of co-stimulatory molecules that activate T lymphocytes. Specifically, migrating dendritic cells, derived from Langerhans' cells that have captured antigen, enter the lymph node through efferent lymphatics and localize in lymphoid organs where they present antigenic peptides to T lymphocytes that facilitate B lymphocyte activation and the production of antibody-secreting plasma cells. In addition to their function as antigen-presenting cells, they are also important in the process of negative selection in the thymus and in the maintenance of peripheral tolerance. The four types of antigen-presenting dendritic cells and their locations are listed in Table 5-4. Circulating dendritic cells, also known as "veiled cells," make up less than 1% of peripheral blood mononuclear cells. The second type of dendritic cell, the follicular dendritic cell, is primarily located in lymphoid follicles. These cells are not bone marrow derived, do not express MHC class II molecules, and do not function as an antigen-presenting cell. Follicular dendritic cells have Fc receptors and receptors for C3b. They store antigen-antibody and antigen-C3b complexes and are thought to be involved in the development and maintenance of memory B lymphocytes.

NK cells are nonspecific cytotoxic cells that are important in early responses to tumor cells and viral infections. NK cells are bone marrow–derived, large granular lymphocytes that make up 5% to 15% of the peripheral blood mononuclear cells. Their size, slightly larger than that of a small lymphocyte, and the presence of abundant granular cytoplasm distinguish them from T lymphocytes (Fig. 5-8). They are commonly referred to as large granular lymphocytes. The cytoplasm of NK cells and cytotoxic T lymphocytes is characterized by cytotoxic granules that contain perforin and granzymes, two potent pathways mediating lysis of the target cell. NK cells and T lymphocytes express numerous similar surface molecules and kill virus infected cells and tumor cells by similar mechanisms. Two membrane molecules, CD16 and CD56, are commonly used to identify NK cells. NK cells express Fc- $\gamma$ -receptors (CD16) and the  $\beta$ -subunit of the IL-2 receptor (CD2). They do not express antigen-specific TCR or CD3 molecules. In contrast to cytotoxic lymphocytes, NK cells are not MHC restricted, are constitutively cytolytic, and do not develop memory cells. Because NK cells are activated early in an immune response and do not require a previous sensitization phase to develop memory cells following activation, they are the cytotoxic cell of innate immunity, the counterpart to the adaptive immune response's cytotoxic T lymphocyte.

201

202

**Fig. 5-7 Dendritic cell functions.** Specialized dendritic cells in the epidermis (Langerhans' dendritic cells) capture antigen via phagocytosis or endocytosis and migrate to regional lymph nodes, where they present peptide fragments of the antigen to naïve T lymphocytes. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-4 Antigen-Presenting Dendritic Cells and Their Primary Location

Dendritic Cells	Location
Langerhans' cells	Skin, mucous membranes, iris, ciliary body
Interstitial dendritic cells	Most major organs
Interdigitating dendritic cells	T-lymphocyte area of secondary lymphoid tissue and thymic medulla
Circulating dendritic cells	Peripheral blood

Although NK cells do not express any antigen-specific molecules, they are very efficient at recognizing and killing altered or virally infected cells. NK cell activity is regulated through activating and inhibitory receptor molecules expressed on their cell surface (Fig. 5-9). These NK cell receptor molecules fall into two distinct categories: the immunoglobulin-like NK receptors and the C-type lectinlike NK receptors. Ligands for these receptors are cell surface molecules whose expression has been altered as a result of infection or damage. Ligands for activating receptors that stimulate NK cell activity commonly include viral and stress-induced proteins. Ligands for inhibitory receptors that block NK cell activity, most commonly involve

202

class I MHC molecules. A decreased expression of class I MHC molecules makes cells susceptible to NK cell-mediated lysis. A decrease in MHC class I expression often occurs in virus-infected cells and in neoplastic cells, making them susceptible to attack by NK cells. Normal cells are protected from NK cell killing because all nucleated cells express class I MHC molecules. This is an oversimplification of the “opposing-signals” model of NK cell regulation of how cytotoxic activity is limited to altered self-cells.

203

Recent studies on the molecular mechanisms of NK cell regulation indicate that the absence of an inhibitory stimulus by itself is insufficient for triggering NK cell killing. NK cells also require triggering of activating receptors. Several activating receptors have been identified. One is the NKG2D receptor, a C-type lectin-like molecule that recognizes a number of stress-induced proteins. These stress-induced proteins are normally only constitutively expressed in the intestinal epithelium or as a result of cellular distress caused by infection or neoplastic transformation. There are a number of additional activating receptors, some of which recognized viral proteins, that are structurally similar to class I MHC molecules.

Fig. 5-8 Activated natural killer cell with numerous cytoplasmic granules that are characteristic of these large granular lymphocytes. (Courtesy Dr. Noelle Williams, Department of Pathology, University of Texas Southwestern Medical School, Dallas.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Because NK cells express Fc- $\gamma$ -receptors (CD16), they can also function in antibody-dependent cellular cytotoxicity (ADCC). In the case of NK cells, ADCC allows for antibody-bound targets to be identified and targeted for NK cell-induced lysis.

NK cells also facilitate the early response to viral infections not only by responding to cytokines produced early in a viral infection, but also by producing cytokines that help direct the immune response. NK cells are activated by IFN- $\alpha$  and IFN- $\beta$ , released by virus-infected cells, and by IL-12, released by macrophages. Following activation NK cells have the ability to produce IFN- $\gamma$ , a major cytokine directing the development of T<sub>H</sub> 1-type immune response early in the infection. IL-2 and IL-15 stimulate NK cell proliferation, and IL-12 enhances NK cell killing.

**Fig. 5-9 Regulation of natural killer (NK) cell activity through activating and inhibitory receptors.** *MHC, Major histocompatibility complex. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)*

### 5.3.2 CYTOKINES: MESSENGER MOLECULES OF THE IMMUNE SYSTEM

#### 5.3.2.1 GENERAL PROPERTIES OF CYTOKINES

Cytokines make up a vast group of low molecular weight soluble glycoprotein proteins that are produced by immune and nonimmune cells, are largely produced locally, and act locally to direct the immune response.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The expression of cytokine receptors and their respective ligands is highly regulated and contributes to the complexity of the systemic organization of the immune response. Cytokines are involved in every aspect of leukocyte biology and the immune response and are essential to leukocyte development, recirculation, differentiation, and activation and in maintaining self-tolerance. Cytokines can influence the cytokine-producing cell itself (autocrine), other cells present locally (paracrine), or distant cells (endocrine) (see [Fig. 12-1](#)). Cytokines use common signal transducing pathways, converting an extracellular signal through a cell surface receptor to activate or inhibit the target cell.

203  
204

The nomenclature of cytokines has evolved from a system that originally named them according to their cellular source (e.g., lymphokine from lymphocytes and monokines from monocytes) to one that named them according to not only the cellular source but also the target cell (e.g., interleukin, a cytokine produced by a leukocyte that influences another leukocyte) or to the primary function (e.g., chemokine, a cytokine that affects chemotaxis). As cytokines were characterized, it became apparent that they have pleiotropic, redundant, synergistic, and antagonistic features that do not allow for such a simplistic classification scheme. More recently, cytokines and their receptors have been classified based on their molecular structure and common signaling pathways. Many cytokines share a similar,  $\alpha$ -helix structure that is also shared by their respective receptors and are classified as type I cytokines and receptors. As will be discussed later, the classification of cytokines and cytokine receptors according to their structural similarities allowed for the identification of the cause of the profound cytokine defects associated with x-linked severe combined immunodeficiency disease in humans and dogs. Unfortunately, type I cytokines also have now been found to include other regulatory proteins, such as growth hormone, prolactin, erythropoietin, thrombopoietin, and leptin. Type II cytokines include type I interferons (IFN- $\alpha$  and IFN- $\beta$ ), type II interferon (IFN- $\gamma$ ), and the IL-10 family of cytokines.

The breadth and depth of knowledge regarding the function, regulation, and control of cytokines is overwhelming; however, an overview of the major cytokines and their primary functions is important for understanding the pathogenic mechanism of many disease processes. Some of the major cytokines and their primary biologic activities are presented here and in [Chapters 3 and 4](#) as they pertain to acute and chronic inflammatory responses.

Cytokines that broadly influence innate and adaptive immune responses include IL-1, interferons (type 1), IL-6, and TNF- $\alpha$ . These cytokines are produced and influence a wide array of cell types. Cytokines that are involved in hematopoiesis and lymphocyte development include IL-2, IL-3, IL-4, IL-5, IL-12, IL-15, TGB- $\beta$ , and granulocyte-macrophage colony-stimulating factor (GM-CSF) to mention a few. Chemokines are a large group of cytokines that influence leukocyte development, trafficking, and function. They are organized into subfamilies, with distinct functions, based on the position of cysteine residues. The C-X-C subfamily of chemokines is primarily produced by activated macrophages and tissue cells (e.g., endothelium), and the C-C subfamily is largely produced by activated T lymphocytes. Chemokines are responsible for the anatomic localization (“homing”) of lymphocytes within lymphoid and nonlymphoid tissue. Chemokines and the other proinflammatory cytokines are more thoroughly covered in [Chapter 3](#). The most important functional group of cytokines related to the pathogenesis of a number of diseases of immunity are those involved in the regulation of T<sub>H</sub> lymphocytes. As discussed previously, T<sub>H</sub> lymphocytes are classified based on their functional capacity and ability to elicit primarily an antibody response or a cell-mediated immune response rather than on their expression of specific cell markers ([Fig. 5-10](#)). T<sub>H</sub>1 lymphocytes are activated by IL-2 and IL-18 and produce primarily IL-2, IFN- $\gamma$ , and TNF- $\beta$  to direct a cell-mediated immune response. T<sub>H</sub>2 lymphocytes are activated by IL-4 and produce primarily IL-3, IL-4, IL-5, IL-6, IL-10, and IL-13 to direct a humoral immune response. As discussed later in the chapter, the type of response (T<sub>H</sub>1 versus T<sub>H</sub>2 type) may determine if a diseased state will occur. IL-15 regulates the growth and activity of NK cells. As

## Pathologic Basis of Veterinary Disease, 4th Edition

---

indicated in Fig. 5-10, some cytokines, such as IL-10 and TGF- $\beta$ , down-regulate immune responses. In summary, cytokines produced by the T<sub>H</sub>1 or T<sub>H</sub>2 subset of lymphocytes not only promote the activation and functional capacities of the subset that produces them (autocrine effect), they also inhibit the development and activity of the other subset. This is known as cross-regulation and has important implications with regard to protective immune responses and adverse immune responses, as will be discussed later.

Finally, a number of cytokine inhibitors identified and one of the more studied ones include a factor called IL-1 receptor antagonist, which is produced by macrophages, hepatocytes, and keratinocytes. This factor inhibits the local and systemic effects of IL-1 by blocking the IL-1 receptor. Another group of inhibitors are the soluble cytokine receptors, which are the enzymatic product of cleavage of the extracellular domain of cytokine receptors that bind their respective cytokines, preventing interaction with the membrane-bound receptor form. The best characterized soluble cytokine receptor is the soluble IL-2 receptor. A number of pathogenic organisms have adapted this as an evasion strategy by producing cytokine-binding proteins or mimics to influence the development of the immune response. Although soluble receptors have been identified in a number of human diseases, their exact role remains to be determined.

5.3.3

### STRUCTURE AND FUNCTION OF HISTOCOMPATIBILITY ANTIGENS

The MHC represents a complex of genes that encode specialized molecules involved in intercellular recognition and the distinguishing of self from nonself. These cell surface molecules have immunologic and nonimmunologic functions. The histocompatibility designation originated from the identification of these molecules in determining the compatibility of transplanted tissues. The MHC is an essential component in humoral and cell-mediated immunity. Most T lymphocytes only recognize fragments of antigen when they are bound to MHC molecules, and this requirement is the basis for MHC restriction. The repertoire of MHC molecules is genetically controlled and determines an individual's ability or inability to respond to specific antigens. MHC molecules are present throughout vertebrates and are maintained in gene clusters, each of which encodes different MHC products, which are linked. The primary function of cell surface MHC molecules is to bind peptide fragments of foreign proteins for presentation to antigen-specific T lymphocytes. There are three major classes of genes, and these encode for MHC molecules that are grouped according to their structure, tissue distribution, and function. Class I and class II genes encode cell surface molecules. Class III genes encode components of the complement system, enzymes 21-hydroxylase A and B, cytochrome p450, tumor necrosis factor (TNF)- $\alpha$ and TNF- $\beta$ , and heat shock protein 70.	204 206
---	------------

**Fig. 5-10 Cross-regulation of immunity.** Cross-regulation of  $T_H1$  and  $T_H2$  lymphocytes in part determines if an immunity is primarily a cell-mediated response or a humoral response.  $T_H1$  lymphocytes, activated primarily by interleukin (IL)-12 and IL-18, promote cell-mediated immunity (CMI) by activating macrophages and cytotoxic T lymphocytes.  $T_H2$  lymphocytes, activated primarily by IL-4, promote humoral immunity by producing cytokines that activate B lymphocytes to develop into antibody-secreting plasma cells.  $T_H2$  lymphocytes also produce cytokines that activate mast cells and eosinophils in the pathogenesis of allergic diseases. The cross-regulation of  $T_H1$  and  $T_H2$  lymphocytes provides an inverse relationship between cell-mediated and humoral immunity. *IFN- $\gamma$* , Interferon- $\gamma$ ; *Ig*, immunoglobulin; *NK*, natural killer; *TNF- $\beta$* , tumor necrosis factor- $\beta$ . ## Pathologic Basis of Veterinary Disease, 4th Edition

MHC class I molecules are present on all nucleated cells (and platelets in some species). Their major function is presentation of peptide fragments of antigens to cytotoxic T lymphocytes ( $CD8^+$ ). This requirement results in  $CD8^+$  lymphocytes being MHC class I restricted. MHC class I molecules are further subdivided into highly polymorphic loci, referred to as Ia, and relatively nonpolymorphic loci, referred to as Ib, Ic, and Id. Each class I molecule is composed of a heterodimer consisting of a polymorphic  $\alpha$ -chain that is linked to a nonpolymorphic  $\beta_2$ -microglobulin. The extracellular region of the  $\alpha$ -chain consists of three domains ( $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$ ). The  $\alpha_1$  and  $\alpha_2$  domains form a groove where the peptide fragments bind the MHC molecule (Fig. 5-11). Although MHC class I molecules differ in their ability to bind peptide fragments, they are not as restrictive as antibodies and TCRs. The intracellular processing of antigen into peptide fragments, the association of those fragments with MHC class I molecules, and their transport to the cell surface is a complex process.

Fig. 5-11 Schematic diagram and crystal structures of class I and II major histocompatibility complex (MHC) molecules. (Courtesy Dr. P. Bjorkman, California Institute of Technology, Pasadena.)

Antigen uptake by antigen-presenting cells is by phagocytosis or endocytosis. Antigen processing is the degradation of an antigen into peptide fragments, which are complexed with MHC molecules. Antigen presentation is the transport of the peptide-MHC complex to the membrane, where they are displayed. Antigens can arise intracellularly (endogenous) and extracellularly (exogenous) and the immune system most effectively eliminates these antigens through the elaboration of cytotoxic T lymphocytes or secretion of antibody. The immune system uses two different processing pathways for antigen processing and antigen presentation. Intracellular antigens are processed in a cytosolic pathway and presented in association with MHC class I molecules (Fig. 5-12). Extracellular antigens are processed in an endocytic pathway and presented in association with MHC class II molecules. Endogenous antigens are degraded into small peptide fragments within the cytoplasm by the proteasome complex. Peptide fragments are transported to the endoplasmic reticulum (ER) by an adenosine triphosphate-binding peptide transporter, TAP. Within the ER, the newly synthesized MHC class I  $\alpha$ -chain and associated  $\beta_2$ -microglobulin bind the antigenic peptide and form a complex that is transported from the ER to the Golgi and then to the plasma membrane for presentation to  $CD8^+$  cytotoxic T lymphocytes. The antigen recognition molecule of the cytotoxic T lymphocyte ( $T_C$ )

206

207

## Pathologic Basis of Veterinary Disease, 4th Edition

recognizes the MHC-peptide complex by means of its CD8 molecule, which functions as a co-receptor, binding to the nonpolymorphic  $\alpha_3$  domain of the MHC class I heavy chain. Because cytotoxic T lymphocytes only recognize peptides when they are presented as a complex with MHC class I molecules, they are referred to as being MHC class I restricted. MHC restriction is the result of positive selection of lymphocytes during T-lymphocyte development in the thymus. Portions of some antigens, those portions not processed for presentation, and in some cases entire antigens are completely degraded by exopeptidases of the antigen-presenting cell into amino acids and do not initiate an immune response. Endogenous antigens are most frequently encountered during viral infections and thus cytotoxic T lymphocytes are an important defense mechanism for eliminating virally infected cells.

**Fig. 5-12 Antigen processing and presentation by an antigen-presenting cell, and antigen recognition by T lymphocytes. (A class I major histocompatibility complex [MHC]–restricted CD8<sup>+</sup> lymphocyte is depicted.)** ER, Endoplasmic reticulum; TCR, T-cell receptor. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Class II molecules have a variable tissue distribution depending on the species of domestic animal, but in general they are present on antigen-presenting cells (B lymphocytes, dendritic cells, and macrophages) and can be induced on T lymphocytes, keratinocytes, and endothelial cells by IFN- $\gamma$ . There are significant species differences with regard to the constitutive expression of MHC molecules. The major function of MHC class II molecules is the induction of helper T lymphocytes. Class II MHC molecules are heterodimers consisting of an

## Pathologic Basis of Veterinary Disease, 4th Edition

---

$\alpha$ -chain and a  $\beta$ -chain. The antigen binding site of the class II molecule, unlike that of the class I molecule, is formed by portions of both the  $\alpha_1$  and  $\beta_1$  domain. Additionally, as with the class I MHC molecules, polymorphism of the class II MHC molecules is associated with determining an individual's response to antigens of infectious organisms (see next section). Peptides that bind to class II MHC molecules are in general derived from exogenous antigens, which have been internalized and processed within endosomes and lysosomes of antigen-presenting cells. Antigen-presenting cells can internalize antigen by phagocytosis or endocytosis (receptor mediated or pinocytosis). Macrophages are the only cell type capable of both, as other antigen-presenting cells are poorly phagocytic. Extracellular antigens are processed into peptide fragments in an endocytic pathway and presented in association with MHC class II molecules on the cell membrane. During the synthesis of a class II molecule within the ER, it associates with another protein called the invariant chain, which prevents the molecule from binding endogenously derived peptides. The complex is then transported from the ER to the Golgi complex and into an endocytic compartment (vesicles) that contains the antigenic peptide fragments derived from exogenous antigens. Proteolytic cleavage of the invariant chain allows for the association of the peptide fragment with the class II MHC molecule. The peptide–class II MHC complex is then transported to the cell surface for presentation to CD4<sup>+</sup> T helper lymphocytes. The CD4 molecule acts as a co-receptor for induction of T<sub>H</sub> cell activation. Because T-helper lymphocytes only recognize peptides when

207

208

they are presented as a complex with class II MHC molecules, they are referred to as being class II MHC restricted. It is worth mentioning that of the two scientists, Peter Doherty and Rolf Zinkernagel, who received the Nobel Prize in Medicine in 1996 for discovering MHC restriction, Dr. Doherty is an Australian veterinarian.

MHC molecules are important in regulating T-lymphocyte development in the thymus and in the peripheral lymphoid tissues determining specific responses to different forms of antigens. During the development and maturation process in the thymus, only T lymphocytes capable of recognizing self-MHC molecules are selected (positive selection) for export to the peripheral lymphoid tissues. These developmental processes influence an individual's T-lymphocyte repertoire, which is the functional population that influences immunity. An individual's ability to mount an effective immune response is determined in part by his or her ability to recognize endogenous and exogenous antigens and their MHC haplotype. Thus in one case, the association of an antigenic peptide fragment with a specific MHC molecule may result in a protective antibody response with elimination of an infectious agent, whereas in another case, the association of an anti-genic peptide fragment with a specific MHC molecule may result in an inappropriate immune response to an innocuous antigen, producing an allergic reaction.

The organization (chromosomal location) and characterization (number of loci, etc.) of the MHC of each species of domestic animals appears to be fairly conserved and present in higher vertebrates and mammals. Most mammalian species studied have class I, II, and III genes, with differences between species being the arrangement and number of genetic loci comprising the MHC. In general, class I genes are more closely related within a species than between species, and the avian MHC is smaller and less complex, with many genes found in the mammalian MHC being absent. Although it is beyond the scope of this chapter to discuss the details regarding the differences between domestic species, the preceding overview is relevant to most domestic species.

### 5.3.3.1

#### MAJOR HISTOCOMPATIBILITY COMPLEX AND DISEASE ASSOCIATION

The MHC influences transplant acceptance or rejection, immune responsiveness, and the pathogenesis of a number of diseases. The MHC represents a complex of genes that encode specialized molecules involved in antigen presentation and thus regulate immune responses. The ability of the immune system to respond to an antigen is determined in part by the binding of peptide fragments to MHC molecules, which are then presented on the surface of antigen-presenting cells. There is a growing body of information associating

## Pathologic Basis of Veterinary Disease, 4th Edition

---

certain MHC alleles with increased or decreased susceptibility to certain diseases (Table 5-5). Because the MHC genes of most domestic species are not well characterized, it is difficult to distinguish if the observed effects are due to the MHC itself or to other tightly linked genes. These conclusions are generally the result of an observation that some MHC alleles occur at a higher frequency among individuals affected with the disease, as compared with the general population. The association of an increased risk with certain MHC alleles is never the sole basis for determining if an individual will develop the disease, as often other hereditary and environmental factors also play an important role. The diseases most often associated with certain MHC alleles have a pathogenesis that incorporates a significant immunologic component. The types of diseases identified are diverse; however, they frequently include autoimmune, infectious, and allergic diseases. Additionally, MHC diversity may increase or decrease the susceptibility to infectious diseases. There is evidence that MHC polymorphisms may significantly impact disease resistance and is best illustrated in species in which there is a loss of MHC diversity attributed to a limited breeding pool of animals. In the case of the cheetah and Florida panther, the current breeding stocks of both species are derived from a limited genetic pool thus resulting in reduced MHC diversity. In both species, there is an increased susceptibility to infectious agents that is not seen in other species of big cats.

Although there are a number of hypotheses to account for the role of MHC molecules in disease susceptibility, the actual mechanisms remain elusive. The most often hypothesized mechanism is attributed to the role of MHC alleles in determining responsiveness or nonresponsiveness to a particular pathogen. On the one hand, through antigen presentation and activation of cytotoxic or helper T lymphocytes, it determines whether or not a protective immune response is generated to a particular pathogen. On the other hand, certain MHC alleles may encode molecules that are used by infectious agents, as in the case of receptors for viruses or bacterial toxins, and facilitate their infectivity or pathogenicity.

### 5.4 DISORDERS OF THE IMMUNE SYSTEM

As has been discussed, immunity is a complex defensive system of recognition and effector mechanisms for protecting the host from infectious pathogens and cancer. During the normal immune response, there are mechanisms for eliminating the inciting foreign antigen, and associated with this is some degree of tissue damage that elicits an inflammatory response of appropriate duration and severity for the antigen. However, there are a number of instances in which the immune response elicits an inflammatory response that is not appropriate to the inciting antigen and these fall into three general categories. The largest category is the hypersensitivity reactions, which are associated with a large number of diseases covered throughout this text. The second category is the autoimmune diseases, in which the immune response is inappropriately directed at a self-antigen, resulting in damage to normal organs or tissue. The third category is the immunodeficiency diseases, in which a genetic or acquired defect results in an inability to mount an immune response and thus control infections, resulting in severe systemic inflammation. The chapter will now focus on general features of immunologic tissue injury, with discussion of some specific immunologic diseases that are attributable to disorders of the immune system. Finally, we will conclude with a discussion of amyloidosis, a condition that is the result of a number of mechanisms, some of which have an immunologic basis.

### 5.4.1

#### MECHANISMS OF IMMUNOLOGIC TISSUE INJURY: HYPERSENSITIVITY REACTIONS

A hypersensitivity reaction is defined as the altered reactivity to a specific antigen that results in pathologic reactions upon the exposure of a sensitized host to that specific antigen. The designation of these immune responses as “hyper” is somewhat of a misnomer because the reactions elicited are better characterized as inappropriate or misdirected responses. An immune response can be either beneficial or harmful. By characterizing hypersensitivity responses as inappropriate or misdirected, we are not implying that these responses are any different from those that occur as a normal “beneficial” defense mechanism. To state it more clearly: If the immune response is beneficial it is immunity, and if it is harmful it is hypersensitivity. All hypersensitivity reactions are characterized by sensitization and effector phases. The sensitization phase requires that the host must have had either a previous exposure or a prolonged exposure to the antigen such that he or she can develop an immune response to the inciting antigen. The pathology associated with hypersensitivity reactions occurs in the effector phase and is most commonly manifested as an inflammatory reaction or as cell lysis.

Hypersensitivity reactions have historically been classified on the basis of the immunologic mechanism that mediates the disease, as type I, type II, type III, or type IV. Type I, II, and III are mediated by antibody, and type IV is mediated by macrophages and T lymphocytes. Type I is also known as immediate type hypersensitivity and most often is the result of an IgE response that is directed against an environmental or exogenous antigen (also known as an allergen). The result is the release of vasoactive mediators from IgE

209

210

## Pathologic Basis of Veterinary Disease, 4th Edition

---

sensitized mast cells, and these mediators produce an acute inflammatory response. Type II is also known as cytotoxic hypersensitivity and most often occurs when IgG or IgM is directed against either an altered self-protein or a foreign antigen bound to a tissue or cell. The result can lead to either destruction of the tissue or cell by antibody-dependent phagocytosis (ADCC), complement-mediated lysis, or altered cellular function without evidence of tissue or cell damage. Type III is also known as immune complex hypersensitivity and is due to the formation of insoluble antibody-antigen complexes (also known as immune complexes). The result is activation of the complement system and the development of an inflammatory reaction at the sites of immune complex deposition. Type IV is also known as delayed-type hypersensitivity (DTH) and is the result of activation of sensitized T lymphocytes to a specific antigen. The resulting immune response is either mediated by direct cytotoxicity or by the release of cytokines that act primarily through macrophages. This original classification, as proposed by Gell and Coombs, was based largely on the primary initiating event involved in the individual reactions and not on the actual pathogenesis as it relates to what is seen clinically or pathologically. Although the original classification of hypersensitivity reactions is still valid, “newer” versions that are based on the pathogenesis better illustrate the complexity of these reactions and the specific pathology (lesions) associated with them. For the purposes of our discussion, we will use the original version of the Gell and Coombs classification presented in [Table 5-6](#), understanding that many of the diseases associated with hypersensitivity reactions are actually complex and may involve more than one type. In humans, genetic mapping studies of most diseases characterized by a hypersensitivity reaction suggest that there are disease-associated susceptibility genes, further supporting the complex pathogenesis of these diseases. Finally the pathogenesis of many diseases rarely involves a single hypersensitivity reaction, and in fact some diseases may begin as an immediate hypersensitivity but progress to be predominantly DTH. For clarity, the hypersensitivity diseases are discussed in the context of their predominant mechanism except when it is appropriate to elaborate on the progression of a disease.

211

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-6 Mechanisms of Hypersensitivity Diseases

Type	Immunologic Component	Antigen	Prototype Disorder	Immune Mechanisms	Pathologic Lesions
Immediate (type I) hypersensitivity	IgE mediated	Allergens	Anaphylaxis; allergies (atopic forms)	Production of IgE antibody → immediate release of vasoactive amines and other mediators from mast cells; recruitment of inflammatory cells (late-phase reaction)	Vascular dilation, edema, smooth muscle contraction, mucus production, inflammation
Antibody-mediated (type II) hypersensitivity	IgG and IgM mediated	Cell- or matrix-associated antigens  Cell surface receptor	Autoimmune hemolytic anemia; neonatal isoerythrolysis; transfusion reactions; drug reactions; Pemphigus	Production of IgG, IgM → binds to antigen on target cell or tissue → phagocytosis or lysis of target cell by activated complement or Fc receptors; recruitment of leukocytes	Cell lysis; inflammation
Immune complex-mediated (type III) hypersensitivity	IgG and IgM mediated	Soluble antigen (e.g., bacterial and viral antigens)	Systemic lupus erythematosus; some forms of glomerulonephritis; serum sickness; Arthus reaction	Deposition of antigen-antibody complexes → complement activation → recruitment of leukocytes by complement products and Fc receptors → release of enzymes and other toxic molecules	Necrotizing vasculitis (fibrinoid necrosis); inflammation
Cell-mediated (type IV) hypersensitivity	T-lymphocyte mediated	Soluble antigen (e.g., bacterial and viral antigens) Contact antigens  Cell-associated antigen	Contact dermatitis; transplant rejection; tuberculosis; chronic allergic diseases	Activated T lymphocytes → (i) release of cytokines and macrophage activation; (ii) T-lymphocyte mediated cytotoxicity	Perivascular cellular infiltrates; edema; cell destruction; granuloma formation

## Pathologic Basis of Veterinary Disease, 4th Edition

5.4.1.1

### TYPE I HYPERSENSITIVITY (IMMEDIATE HYPERSENSITIVITY)

Type I hypersensitivity reactions are most commonly the result of an IgE-mediated immune response directed against environmental antigens (i.e., allergens) and parasite antigens. Harmful IgE-mediated responses to innocuous environmental antigens resulting in allergic reactions are termed hypersensitivity, whereas similar IgE-mediated protective responses to parasite antigens are considered immunity. This distinction emphasizes the fact that these are not unique immunologic reactions but rather misdirected or inappropriate “normal” immune responses. Type I hypersensitivity occurs in a previously sensitized host and is initially manifested as acute inflammatory process that occurs within minutes (“immediate hypersensitivity”) of exposure to the specific antigen. In many instances the reaction progresses from an early acute inflammatory response to a late phase response and/or chronic inflammatory lesion that persists (Figs. 5-13 and 5-14). The basic pathogenesis involves a sensitization phase and an effector phase. The sensitization phase occurs during the initial exposure to an antigen when the host develops an antigen-specific IgE response, which results in sensitization of the host by the binding of the antigen-specific IgE to Fcε receptors on the surface of mast cells (Fig. 5-15). The host is now sensitized, and either through a second exposure or prolonged initial exposure to the IgE-specific antigen, there is cross-linking of two or more IgE molecules on the surface of the mast cell. This results in its activation and release of preformed and newly synthesized mediators, resulting in the effector phase. The effector phase can be limited to an acute inflammatory reaction (occurring within minutes), resulting primarily from the release of mast cell mediators, or can progress to a late-phase reaction (over a period of hours), or to a chronic reaction (persisting for days to years). The acute reaction is characterized by responses associated with release of preformed vasoactive amines from the mast cell and includes increased vascular permeability, smooth muscle contraction, and influx of inflammatory cells. The late phase and chronic reactions, often associated with repeated or prolonged antigen exposures, are largely the result of a more intense inflammatory cell infiltration (primarily eosinophils, neutrophils, macrophages, and T lymphocytes) and tissue damage. Because the mast cell is central to the pathogenesis of a type I hypersensitivity reaction, we will review their biologic features and primary functions.

211

212

**Fig. 5-13 Immediate hypersensitivity reaction.** **A**, Early reaction (minutes) is characterized by mast cell degranulation and release of preformed vasoactive substances that cause vasodilation and increased vascular permeability, resulting in edema of interstitial tissue. **B**, As the lesion progresses to the late phase (hours), the inflammatory infiltrate is primarily composed of eosinophils and fewer lymphocytes and neutrophils. (**A and B**, Courtesy Dr. Daniel Friend, Department of Pathology, Brigham and Women's Hospital, Boston.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Mast cells are a heterogeneous population of bone marrow–derived cells that reside in vascularized tissue. 212

Mast cells are easily identified by their abundant metachromatic cytoplasmic granules. Metachromasia is defined as the staining of a tissue component so that the color (absorption spectrum) of the tissue-dye complex differs from the color of the original dye and of the other stained tissue. In other words, the metachromatic substance is a different color from those of the dye and the other stained tissue. For example, toluidine blue is a metachromatic dye, and it stains most tissues blue, but mast cell granules are purple. Other commonly used metachromatic dyes include methylene blue and thionine. Wright's and Giemsa stains are dye mixtures that include a metachromatic dye. Mast cells can be divided into mucosal and connective tissue subpopulations, not only based on their location but also on their phenotypic, morphologic, histochemical, and functional characteristics. This suggests that individual subpopulations of mast cells may have specific functions in normal and pathologic responses that are a result of their activation. The tyrosine kinase receptor, c-kit, expressed on mast cells, their precursors, and its ligand—stem cell factor (SCF)—is essential to mast cell development and function. Alterations in c-kit have been used to molecularly identify poorly differentiated mast cell tumors. 213

**Fig. 5-15 Mast cell degranulation and activation.** Cross-linking of a sensitized (immunoglobulin E [*IgE*] bound to membrane FcE receptors) mast cell by antigen results in mast cell activation and degranulation. Degranulation results in release of preformed mediators (histamine, proteases, and chemotactic substances). Activation results in synthesis of arachidonic acid from the plasma membrane and the production of prostaglandins and leukotrienes. *ECF*, Eosinophil chemotactic factor; *NCF*, neutrophil chemotactic factor; *PAF*, platelet-activating factor. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Mast cell activation can occur through a number of immunologic and nonimmunologic mechanisms. In addition to the activation of mast cells through cross-linking of membrane-bound IgE by antigen, other substances and stimuli can also activate mast cells. Mast cells can be activated by FcE receptor-independent mechanisms, including cytokines (IL-8), complement products (the anaphylatoxins C3a and C5a), drugs (nonsteroidal antiinflammatory drugs, codeine, and morphine) and physical stimuli (heat, cold, and trauma). Non-IgE-mediated activation of mast cells is referred to as an anaphylactoid reaction, whereas the IgE-mediated activation is referred to as type I hypersensitivity. There are species and tissue differences in the how type I reactions are manifested, and these are attributable to the types and proportions of mediators produced by the mast cell. Mast cells are a heterogeneous population of cells with regard to their structure and function. Although they are generally divided into mucosal-based and connective tissue-based populations, in either case they are primarily found adjacent to blood vessels and nerves where their mediators have their greatest influence. Mediators released by mast cells are broadly classified as preformed (primary) or newly synthesized (secondary), and as presented in [Table 5-7](#) and [Fig. 5-15](#), they influence local tissues and other cell types. Primary mediators are stored in cytoplasmic granules and include the vasoactive amines histamine, serotonin, and adenosine; chemotactic factors for eosinophils and neutrophils; enzymes including neutral proteases and acid hydrolases; and proteoglycans, such as heparin and the chondroitin sulfates. Newly synthesized mediators consist largely of the lipid mediator products of cyclooxygenase and lipoxygenase metabolism of arachidonic acid (see [Chapter 3](#)), a number of cytokines and platelet-activating factor (PAF). The major products of arachidonic metabolism are the prostaglandins and leukotrienes, of which prostaglandin D<sub>2</sub> and leukotrienes C<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub> are most important. The major cytokines released from mast cells during a type I reaction include IL-4, IL-5, IL-6, and TNF- $\alpha$ . IL-4 and IL-5 contribute to B-lymphocyte activation and IgE synthesis. IL-5 is chemotactic for eosinophils. IL-6 and TNF- $\alpha$  are involved in the pathogenesis of shock during a systemic type I (anaphylactic) reaction. The biochemical events involved in IgE-mediated activation and mediator release by mast cells are similar to those described for leukocyte activation in [Chapter 3](#). The primary actions of preformed and newly synthesized mediators are attributable to cellular infiltration, vasoactive responses, and smooth muscle contraction. PAF, first identified as an initiator of platelet aggregation and degranulation, functions not only in the acute phase by increasing vasodilation and vascular permeability, but is also important early in the late phase by recruiting and activating inflammatory cells. Finally, it is of note that recent studies have identified TLR pathways that mediate interactions between dendritic cells, T lymphocytes, and mast cells, thus modulating type I responses.

213

214

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-7 Summary of Mast Cell Mediators and Their Actions

Action	Mediator
Vasodilation, increased	Histamine
Vascular permeability	PAF Leukotrienes C <sub>4</sub> , D <sub>4</sub> , E <sub>4</sub> Neutral proteases that activate complement and kinins Prostaglandin D <sub>2</sub>
Smooth muscle spasm	Leukotrienes C <sub>4</sub> , D <sub>4</sub> , E <sub>4</sub> Histamine and Giemsa Prostaglandins stains are dye mixtures that
Cellular infiltration	PAF Cytokines (e.g., TNF) Leukotriene B <sub>4</sub> Eosinophil and neutrophil chemotactic factors (not defined biochemically) PAF
PAF, Platelet-activating factor; TNF, tumor necrosis factor.	

A type I reaction begins as an acute inflammatory reaction mediated largely by the vasoactive amines released by degranulation of mast cells. It is during this early stage that mast cells also release large quantities of chemotactic factors and cytokines. These mediators recruit and activate the inflammatory cells that will not only sustain the inflammatory response in the absence of antigen, but also cause tissue damage. The immediate response is characterized by increased blood flow, increased vascular permeability (edema), and smooth muscle spasm. As the reaction progresses, additional leukocytes are recruited, and they release biologically active substances that cause cell damage. Of these leukocytes, eosinophils are particularly important.

Eosinophils are recruited to the sites of type I hypersensitivity reactions by chemokines, such as eotaxin, and their survival is influenced by IL-3, IL-5, and GM-CSF, which are largely derived from T<sub>H</sub>2 lymphocytes.

Eosinophils recruited during the early response play an active role in the late phase response by releasing components of their granules, synthesizing lipid mediators, and producing cytokines. The basic proteins released by eosinophils are toxic to parasites and host tissue. In particular, eosinophil major basic protein is toxic not only to parasites but also to tumor cells and normal cells. These proteins contribute to the epithelial cell damage associated with chronic type I reactions. Lipid mediators synthesized by activated eosinophils include PAF, leukotrienes, and lipoxins. Cytokines produced and released by eosinophils include growth factors, chemokines, cytokines involved in inflammation and repair, and regulatory cytokines. Macrophages and lymphocytes also participate in the late phase response to varying degrees.

Epithelial cells further contribute to the inflammation by becoming activated and producing factors that recruit and activate additional inflammatory cells. It is this complex series of cell activation, recruitment, and mediator release that amplifies the immune response and sustains the inflammatory reaction long after the antigen has gone.

The factors that determine whether a host will develop a type I hypersensitivity reaction are complex. The genetic makeup of the host and the dose and route of antigen exposure are most important. These factors influence whether the individual will have a T<sub>H</sub>1 or T<sub>H</sub>2 response. The development of an IgE-secreting B lymphocyte from an immature (naïve) B lymphocyte is dependent on activated CD4<sup>+</sup> lymphocytes of the T<sub>H</sub>2 type. The cytokines that define a T<sub>H</sub>2-lymphocyte response have important roles in regulating the cells

## Pathologic Basis of Veterinary Disease, 4th Edition

involved in a type I hypersensitivity reaction. IL-3, IL-4, and IL-10 influence mast cell production; IL-4 is involved in isotype switching to IgE; and IL-3 and IL-5 influence eosinophil maturation and activation. IL-13 promotes the production of IgE. The major cytokine that defines a  $T_H1$  response, IFN- $\gamma$ , inhibits the  $T_H2$  response. Thus an animal that develops predominantly a  $T_H2$  response to a particular antigen would be more likely to develop a type I hypersensitivity reaction as compared with one that develops predominantly a  $T_H1$  response. The  $CD4^+$  T lymphocyte plays a central role in the pathogenesis of a type I hypersensitivity. In humans, additional genetic influences can be linked to the human leukocyte antigen (HLA)-linked immune response genes. These genes appear to control allergen-specific IgE responses. As mentioned previously, the association of specific class I MHC molecules with an increased susceptibility to atopy in the dog have been proposed. As with the mast cell and the eosinophil, a role for the  $CD4^+$  T lymphocyte in the late phase response has also been described. Studies suggest that the continued production of  $T_H2$  cytokines contributes to the chronic inflammation associated with some chronic type I hypersensitivity reactions.

214

In summary, type I hypersensitivity is a complex disease process that occurs in sensitized hosts, which can result in three types of responses: (1) an acute inflammatory response, (2) a late phase response, and (3) a chronic inflammatory response. In sensitized hosts, the cross-linking of IgE on the surface of mast cells results in the immediate release of mediators that influence local tissue and recruit additional inflammatory cells. The acute response is dependent on resident mast cells, whereas the late phase and chronic responses are dependent on recruited cells, especially the eosinophil. Central to the pathogenesis of a type I hypersensitivity reaction are the  $T_H2$  lymphocytes and the cytokines they produce, which influence IgE production and the recruitment and activation of leukocytes.

215

Systemic and localized type I hypersensitivity reactions occur in animals. The pathogenesis of many infectious and noninfectious diseases involves the production of IgE and the development of a type I hypersensitivity reaction. Type I hypersensitivity is an allergic reaction that occurs within minutes of exposure to an antigen to which the host has been previously sensitized. Allergy has become synonymous with type I hypersensitivity. By definition, type I hypersensitivity reactions are mediated by IgE. Systemic type I hypersensitivity reactions are called anaphylaxis. Atopy is the genetic predisposition to develop localized type I hypersensitivity reactions to innocuous antigens. Atopy is often limited to an organ or tissue, such as in allergic dermatitis and rhinitis, food allergies, and asthma. Non-IgE-mediated allergic-like reactions are referred to as anaphylactoid reactions.

### 5.4.1.1.1

#### Systemic Type I Hypersensitivity (Anaphylaxis)

Anaphylaxis refers to an acute systemic hypersensitivity reaction to an antigen that is mediated by IgE and involves mast cell activation, resulting in a shocklike state often involving multiple organ systems. The clinical signs and pathology attributable to a systemic anaphylactic reaction vary by species and often correlate to the primary shock organ in its most severe manifestation—death. This variation reflects differences in the distribution of the mast cells, the mediator content of their granules that are unique to individual species, and the primary target tissue. The primary target tissues are blood vessels and smooth muscle. Blood vessel beds and smooth muscles vary in their histamine receptor content, and as such some are more susceptible than others to the influences of histamine. Because of the aforementioned, the early signs of anaphylaxis can be varied. Cutaneous signs include pruritus, hyperemia, and angioedema. Cardiovascular signs include hypotension and an accompanying sinus tachycardia (characteristic of a vasovagal response). Respiratory signs include bronchospasms, laryngeal edema, and dyspnea. As the anaphylactic reaction progresses, hypotension or hypoxia may lead to unconsciousness. Fatal anaphylaxis may occur as the result of asphyxiation secondary to edema of the upper airway, circulatory failure as a

## Pathologic Basis of Veterinary Disease, 4th Edition

---

result of dilation of the splanchnic vascular bed, or hypoxemia as a result of severe bronchospasms. In humans, a body of evidence also implicates human heart mast cells (HHMCs) in myocardial anaphylaxis as a primary mechanism. Other than in cases with upper airway edema or pulmonary hyperinflation (emphysema), there are no pathognomonic lesions of anaphylaxis. The species most sensitive to the development of anaphylaxis is the guinea pig. The most common pathologic findings in most species are pulmonary edema and emphysema, except for dogs, for which the major shock organ is the liver, and severe hepatic congestion and visceral hemorrhage are the most common findings.

The types of antigens that can elicit a systemic anaphylactic reaction are diverse, but most commonly include drugs (especially penicillin-based antibiotics), vaccines, venom of stinging insects, and heterologous sera. Although the greatest risk for the development of an anaphylactic reaction occurs during parenteral administration, it must be noted that in some cases even a small quantity of antigen in a highly sensitized host can elicit a systemic response.

### 5.4.1.1.2

#### Localized Type I Hypersensitivity

In a localized type I hypersensitivity reaction, the clinical signs and pathologic findings are restricted to a specific tissue or organ. Localized reactions most commonly occur at epithelial surfaces, such as the surfaces of the skin and mucosa of the respiratory and gastrointestinal tract. As discussed previously, species differences on the location of mast cells, the mediators contained within them, and the histamine receptor distribution on target tissue may explain the different spectra of diseases seen among individual species.

Allergic dermatitis is a cutaneous manifestation of a type I hypersensitivity reaction that results in inflammation of the skin. The route of exposure to the antigen may be by inhalation, ingestion, or percutaneous absorption. If the allergic dermatitis is thought to have a genetic predisposition, then the disease is referred to as atopic dermatitis. Dietary type I hypersensitivity reactions in the dog and cat more commonly present as a cutaneous disease rather than a gastrointestinal disease. Other common cutaneous manifestations of type I hypersensitivity are flea and other arthropod bites and urticaria and angioedema (hives). All of these diseases are characterized by an acute inflammatory reaction, often perivascular, caused by mediators released from sensitized mast cells. In some instances, as in atopic dermatitis, the lesion may progress to a late phase response or chronic inflammation characterized by more intense inflammatory infiltrates (e.g., atopic dermatitis) or to a type IV hypersensitivity reaction (arthropod bites).

215

Other secondary changes, such as acanthosis, hyperpigmentation, sebaceous gland metaplasia, and pyoderma, occur in long-standing cases or in animals that have significant trauma related to pruritus.

216

Allergic rhinitis is a respiratory manifestation of a type I hypersensitivity reaction that most commonly develops in ruminants. The most common antigens are grass and weed pollens and mold spores (*Micropolyspora faeni*). This disease also frequently progresses from an acute inflammatory disease to a late phase response and chronic inflammation. In cattle, long-standing allergic rhinitis may progress to a type IV hypersensitivity reaction with the formation of nasal granulomas. Mold spores (*Micropolyspora faeni*) are more frequently associated with a type III hypersensitivity reaction, resulting in an allergic pneumonitis (extrinsic allergic alveolitis).

Although an inherited predisposition has been implicated in some species, the exact mode of inheritance remains to be determined. In humans, a link to genes encoding IL-4 and certain MHC antigens, important components of allergic diseases, has been made.

### TYPE II HYPERSENSITIVITY (CYTOTOXIC HYPERSENSITIVITY)

In the original Gell and Coombs classification, the type II hypersensitivity reaction was designated as antibody-mediated cytotoxic hypersensitivity. This type of hypersensitivity most often occurs as the result of the development of antibodies directed against antigens on the surface of a cell or in a tissue, with the result that the cell or tissue is destroyed. Antigens may be either endogenous (normal cellular or tissue protein) or exogenous (e.g., a drug or microbial protein adsorbed to the cell). In some instances, the antigen may be a cell surface receptor and the antibody may activate or block the activation of the cell rather than cause cytotoxicity. The pathogenesis of many immune-mediated and autoimmune diseases is centered on the development of antireceptor or antisurface antigen antibodies and a type II hypersensitivity reaction. The largest group of “cytotoxic” hypersensitivity reactions involves the hematologic diseases, with antibodies directed against antigens present on the surface of red blood cells and platelets. Type II hypersensitivity reactions are mediated by antibodies directed against antigens on the surface of tissue or cells, such that the tissue or cell is destroyed or the function of the cell is altered. Type II hypersensitivity reactions most frequently involve IgM and IgG and occur within hours after exposure in a sensitized host.

There are three basic antibody-mediated mechanisms that result in type II hypersensitivity ([Fig. 5-16](#)). Complement-dependent reactions occur as a result of the complement activating capability of IgG and IgM. Complement activation can mediate cytotoxicity by either the formation of the membrane attack complex, resulting in cell lysis, or the fixation of C3b fragments (opsonization) to the surface facilitating phagocytosis (see [Chapter 3](#)). Antibody-dependent reactions can similarly opsonize cells, facilitating phagocytosis, or result in cell lysis by antibody-dependent cellular cytotoxicity. Opsonization of cells by antibody makes them susceptible to destruction by macrophages, neutrophils, NK cells, and eosinophils, all of which bear Fc receptors. This is commonly referred to as antibody-dependent cellular cytotoxicity (ADCC). Finally, antibodies directed against surface receptors may result in altered cell or tissue function. The antireceptor antibodies can function as agonists, stimulating cell function or as antagonists, blocking receptor function.

Diseases with a type II hypersensitivity pathogenesis are presented in [Table 5-8](#). The physical and biochemical properties of red blood cells, platelets, and leukocytes make them susceptible to cytotoxic reactions. Two properties of red blood cells make them uniquely susceptible to being involved in type II reactions. First, their surface contains a complex array of blood group antigens that can become targets of antibody responses as is commonly the case in transfusion reactions or immune-mediated hemolytic disease of the newborn. Second, the biochemical properties of red blood cells make them prone to adsorb substances, such as drugs or antigenic components of infectious agents or tumors. In these instances, the red blood cell may be either directly targeted because the substance alters a surface protein to an extent that it is now recognized as foreign, or indirectly targeted if there is an antibody response to the substance itself. Finally, in autoimmune forms of hemolytic anemia, agranulocytosis, and thrombocytopenia, there is a breakdown of tolerance and the subsequent development of antibodies to normal cells, and as a result they are destroyed.

The majority of cytotoxic type II diseases result in a decrease or loss of a population of cells (e.g., anemia, thrombocytopenia). Noncytotoxic type II diseases are initially characterized by activation or inhibition of cell or tissue function followed by inflammation, which may cause inflammatory damage to the targeted organ. In a type II reaction, the pathogenesis commonly begins with cell surface antigens eliciting an antibody response, whereby the antibodies bind to the cell and the cell is either lysed or complement components attract phagocytic cells that damage tissues by releasing proteolytic enzymes.

## Pathologic Basis of Veterinary Disease, 4th Edition

5.4.1.3

### TYPE III HYPERSENSITIVITY (IMMUNE COMPLEX HYPERSENSITIVITY)

Type III hypersensitivity is designated as immune complex hypersensitivity. This reaction occurs through the formation of antigen-antibody complexes that activate complement and result in tissue damage (Fig. 5-17). 216 217

The cell or tissue injury is similar to a type II hypersensitivity reaction, although the underlying pathogenesis is different. With a type III reaction, the cell or tissue is being destroyed not because the antibody is being directed against that cell or tissue, but rather because immune complexes either become “stuck” to that cell or are deposited in that tissue. Think of it as an “innocent bystander” reaction: The targeted tissue is not a direct target of the immune response. The pathogenesis begins with the formation of immune complexes that become lodged or are formed in or deposited in tissue and are capable of activating the complement system. 217

Products of complement activation, anaphylatoxins, chemotactic factors, and so on result in neutrophil infiltration and activation. Upon activation, neutrophils release their enzymes and these result in tissue damage. Like type II hypersensitivity reactions, type III hypersensitivity reactions most frequently involve IgM and IgG and occur within hours after exposure in a sensitized host. 218

**Fig. 5-16 Schematic depiction of the three major mechanisms of an antibody mediated injury.** **A**, Opsonization by antibodies (or complement) enhances phagocytosis of antigen by monocyte-macrophage cells. **B**, Antibody can activate the complement system, via the classical pathway, resulting in the elaboration of inflammatory mediators, such as C5a and C3a. **C**, Antibodies against cell receptors can activate (depicted) or inhibit (not depicted) cell functions. *TSH*, Thyroid-stimulating hormone. ## Pathologic Basis of Veterinary Disease, 4th Edition

**Table 5-8 Diseases with a Primary Cytotoxic Hypersensitivity (Type II Hypersensitivity) Pathogenesis**

Disease	Target Antigen	Mechanisms of Disease	Clinicopathologic Manifestations
Autoimmune hemolytic anemia	Erythrocyte membrane proteins (blood group antigens)	Opsonization and phagocytosis of erythrocytes	Hemolysis, anemia
Neonatal isoerythrolysis	Erythrocyte membrane proteins (blood group antigens)	Opsonization and phagocytosis of erythrocytes	Hemolysis, anemia
Autoimmune thrombocytopenic purpura	Platelet membrane proteins (gpIIb/IIIa integrin)	Opsonization and phagocytosis of platelets	Bleeding
Pemphigus diseases	Proteins in intercellular junctions of epidermal cells (e.g., the epidermal cadherin desmoglein 1)	Antibody-mediated activation of proteases, disruption of intercellular adhesions	Vesiculobullous (diseases of the skin)
Vasculitis caused by ANCA	Neutrophil granule proteins, presumably released from activated neutrophils	Neutrophil degranulation and inflammation	Vasculitis
Myasthenia gravis	Acetylcholine receptor	Antibody inhibits acetylcholine binding, down-modulates receptors	Muscle weakness, paralysis
Pernicious anemia	Intrinsic factor of gastric parietal cells	Neutralization of intrinsic factor, decreased absorption of vitamin B <sub>12</sub>	Abnormal erythropoiesis, anemia
Bullous pemphigoid	Collagen type XVII within hemidesmosomes	Antibodies against basal cells	Subepidermal vesicles characterized by basement membrane clefts

ANCA, Antineutrophil cytoplasmic antibody.

Antigen-antibody complexes form as a part of a normal immune response and usually facilitate the clearance of antigen by the phagocytic system without resulting in a type III hypersensitivity reaction. Although a number of factors determine whether a type III reaction will occur, the most important is the relationship of the antibody response to the quantity of antigen. When antibody is in great excess of antigen, the antigen-antibody complexes formed are large and insoluble, and easily removed by the phagocytic system. When antigen is in great excess of the quantity of antibody, the antigen-antibody complexes formed are too small to be capable of becoming lodged in tissues or of activating the complement system. However, when antigen is in slight excess of antibody, these small soluble complexes can become lodged in tissue and activate the complement system. When this type of small soluble antigen-antibody complex is formed in the circulation, their accumulation in tissue is essentially the result of anatomic and physiologic processes and has no immunologic basis. Finally, it has also been suggested that in some instances immune complex hypersensitivity may be the result of the normal phagocytic system being overwhelmed. Immune complex deposition can be localized to a tissue or generalized if the complexes are formed in circulation. Blood vessels, synovial membranes, glomeruli, and the choroid plexus are particularly vulnerable to deposition of immune complexes. The concentration and size of the complexes determine the sites of deposition.

Type III reactions can develop from antibody responses to endogenous or exogenous antigens and immune complexes can be deposited in a number of tissues (Table 5-9). Although a number of diseases of domestic species involve a type III hypersensitivity pathogenesis, a majority of diseases are the result of persistent infections, autoimmune disease, or inhalation of foreign antigen. Organisms that result in persistent

## Pathologic Basis of Veterinary Disease, 4th Edition

infections are often characterized by a weak antibody response and the development of immune complex formation. A number of autoimmune and immune-mediated diseases result in the development of antibody responses to self-antigens or antigens complexed to self-proteins, and these are capable of generating complement activating immune complexes. Immune complexes formed against commonly inhaled environmental antigens can lead to the development of an allergic alveolitis. Type III hypersensitivity reactions are mediated by the formation of antigen-antibody complexes, which results in complement activation leading to an influx of neutrophils and subsequent cell or tissue destruction. Antigen-antibody complexes may be formed in the circulation and lodge in tissue, or may be formed in the tissue directly. The cell or tissue injury is largely determined by physiologic or anatomic properties rather than an immunologic basis. The pathogenesis of a number of diseases of domestic animals have a type III hypersensitivity basis.

219

**Fig. 5-17 A localized type III hypersensitivity reaction (Arthus reaction) in the dermis.** Antigen-antibody complexes, formed at the site of injection, activate the complement system to elaborate components that activate resident mast cells (1) and attract circulating neutrophils (2). Inflammation is the result of tissue damage caused by mediators and enzymes released from both cell types (3). CRI, complement receptor 1. (Adapted from Goldsby RA, Kindt TJ, Osborne BA: *Kuby immunology*, ed 4, New York, 2000, WH Freeman.)

### Localized Type III Hypersensitivity

Localized type III hypersensitivity reactions are best exemplified by the Arthus reaction ([Fig. 5-17](#)). The parenteral administration of an antigen to an animal that has a circulating antibody specific for that antigen results in a localized acute inflammatory response. The complexes are formed either within the tissue at the site of antigen deposition or localized within blood vessels, as the antigen and antibody diffuse into the vascular wall. Early, within hours, the reaction is characterized by margination and emigration of neutrophils to and from the blood vessels and progressively results in tissue and vascular damage. The quantity of antigen-antibody complexes formed in the wall of the vessel determines the extent of the tissue damage. Small quantities of complexes may result in only mild hyperemia and edema. Large quantities of complexes may result in tissue and vascular necrosis as a result of neutrophils releasing the contents of their granules. In some cases, the damage to the wall may be so severe as to cause thrombosis and localized ischemic injury. The Arthus reaction is still used today as an experimental model of a localized type III reaction. Recent studies, using the cutaneous Arthus reaction in complement-deficient mice, document the requirement of Fc receptor (FcR) activation for eliciting an inflammatory response and a revision of the hypothesis of the mechanism of immune complex-mediated inflammation. Complement components, such as C5a, are generated as a result of FcR activation. Conversely, the use of FcR-deficient mice and the Arthus reaction establish the requirement of this receptor, because immune complexes and C3 alone are not sufficient to trigger an inflammatory response and tissue damage.

Many diseases have a progressive clinical course, and immune complex reactions often play a role, even though they may not be involved in the initial immunologic response. There are limited clinical examples of diseases characterized primarily by a localized immune complex reaction. One dramatic example is blue eye in the dog, which is an anterior uveitis that develops in a small percentage of dogs naturally infected with or vaccinated against canine adenovirus type I. Other organs commonly affected by localized immune complex disease include the lung and skin. In the lung, chronic exposure of the lower airways to inhaled antigens can lead to the development of antigen-specific antibodies that form complexes within alveolar walls. This form of allergic lung disease is commonly referred to as allergic pneumonitis (extrinsic allergic alveolitis). Common antigens include spore-forming organisms (e.g., some actinomycetes and fungi). Allergic diseases of the lower airways frequently lead to type II pneumocyte hyperplasia, emphysema, and fibrosis, which are all secondary to inflammation and tissue damage mediated by type III hypersensitivity. Chronic obstructive pulmonary disease (COPD) in horses may be caused in part by a localized type III reaction to spore-forming organisms or dust that results in bronchiolitis (see [Chapter 9](#)). In dogs, staphylococcal infections of the skin may develop a type I, III, or IV reaction. In the case of a type III reaction, a neutrophilic dermal vasculitis is often evident (see [Chapter 17](#)).

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-9 Diseases with a Primary Type III Hypersensitivity (Immune Complex Hypersensitivity) Pathogenesis

Disease	Antigen Involved	Clinicopathologic Manifestations
Systemic lupus erythematosus	DNA, nucleoproteins, others	Glomerulonephritis, arthritis, vasculitis
Blue eye	Canine adenovirus 1 antigen	Anterior uveitis
Equine infectious anemia	Viral antigens	Anemia, thrombocytopenia
Poststaphylococcal hypersensitivity	Staphylococcal cell wall antigens	Dermatitis
Cutaneous vasculitis	Bacterial antigens, viral antigens, drugs	Vasculitis
Poststreptococcal ( <i>Streptococcus equi</i> ssp. <i>equi</i> ) hypersensitivity	M protein	Purpura hemorrhagica, glomerulonephritis
Acute glomerulonephritis	Bacterial antigens; parasite antigens; viral antigens; tumor antigens	Nephritis
Reactive arthritis	Bacterial antigens	Acute arthritis
Arthus reaction	Various foreign proteins	Cutaneous vasculitis
Serum sickness	Various proteins (e.g., foreign serum)	Arthritis, vasculitis, nephritis
Hypersensitivity pneumonitis	Fungal spores, dust	Alveolitis, vasculitis
COPD	Fungal spores, dust	Bronchiolitis
Aleutian mink disease	Viral antigens	Glomerulonephritis, vasculitis
Rheumatoid arthritis	IgG	Erosive polyarthritis

COPD, Chronic obstructive pulmonary disease; IgG, Immunoglobulin G.

### 5.4.1.3.2

#### Generalized Type III Hypersensitivity

When antigen is present in the circulation at appropriate concentrations relative to circulating antibody concentrations (as discussed previously), the result is the formation of immune complexes capable of generating a type III hypersensitivity reaction. Serum sickness is the prototypical disease with a type III hypersensitivity pathogenesis. Early examples of this disease were the result of the administration of heterologous serum, which led to the formation of circulating immune complexes that became lodged primarily in blood vessels, glomeruli, and joints. The blood vessel, glomerulus, or joint was not a target of the immune response but rather an “innocent bystander,” because the resulting inflammation occurred as a result of the complement activating capacity of the immune complexes that lodged there.

The pathogenesis of a systemic immune complex disease is best illustrated in three phases as depicted in Fig. 5-18. The first phase, as discussed previously, occurs when the host develops an antibody response to an antigen such that the ratio of antigen to antibody is appropriate for the formation of small, soluble, circulating complexes that are not adequately cleared by the monocyte-macrophage system. Because the formation of antigen-antibody complexes can be a normal component of an immune response, the presence of immune complexes in circulation by itself is not sufficient to diagnose an immune complex disease. In the second phase, the complexes adhere to cells or lodge in tissues that are uniquely susceptible to circulating immune complexes. The biochemical properties of the antigen-antibody complexes (overall quantity and size, charge, etc.), and the physiologic and anatomic characteristics of some cells and tissues account for their unique susceptibility to immune complex deposition. Other factors may also contribute to the formation or deposition of immune complexes in certain tissues. As an example, in rheumatoid arthritis it has been proposed that lymphocytes within the joint may produce an altered IgG molecule that stimulates the production of rheumatoid factor (anti-IgG). Complexes become lodged within blood vessel walls and extravascular tissues as a result of the increased vascular permeability caused by the anaphylatoxins and vasoactive amines released from neutrophils, activated through the binding of antigen-antibody complexes to complement and Fc receptors on their surface. The result is phase three:

## Pathologic Basis of Veterinary Disease, 4th Edition

---

the activation of the complement system and the development of an acute inflammatory reaction centered on the vasculature. Neutrophils and macrophages are activated similarly through Fc receptors and produce	220
a number of inflammatory cytokines that attract and activate additional inflammatory cells. The	221
inflammatory cells and mediators have been thoroughly discussed in <a href="#">Chapter 3</a> . Immune complexes that lodge in blood vessels, glomeruli, or joints result in vasculitis, glomerulonephritis, and arthritis, respectively. The damage to the vessels also results in damage to the intima and exposure of collagen, which initiates the formation of microthrombi by the activation of the coagulation cascade and platelets.	

**Fig. 5-18 Schematic depiction of the three phases of a systemic type III hypersensitivity reaction.** The first phase results in immune complex formation. In the second phase, the antigen-antibody complexes become lodged in the vessel wall and activate inflammatory cells. The end result, the third phase, is the elicitation of tissue damage and an inflammatory response. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The two primary cell types involved in a type III hypersensitivity reaction are Fc receptor-bearing neutrophils and macrophages (Fig. 5-19). Complement activation leads to the elaboration of factors (primarily C5a) that are chemotactic and attract neutrophils and macrophages to the site. These cells are activated and produce a number of proinflammatory cytokines. Early in the response, these cells release vasoactive amines that cause increased vascular permeability, allowing the immune complexes to lodge within the vessel wall. Many of these phagocytic cells are also stimulated to release their proteolytic enzymes and toxic free radicals, and these processes result in tissue and vascular damage. Platelets also contribute to the developing inflammatory reaction by releasing vasoactive amines and other proinflammatory constituents.

Diseases associated with type III hypersensitivity reactions are most commonly associated with a single exposure to a large quantity of antigen (e.g., administration of heterologous serum or from an immune response to systemic infections) or from continuous exposures to small quantities of antigen as in the case of autoimmune diseases (e.g., rheumatoid arthritis and systemic lupus erythematosus). In either of these instances, the development of type III hypersensitivity is dependent on antigen being in excess of antibody.

5.4.1.4

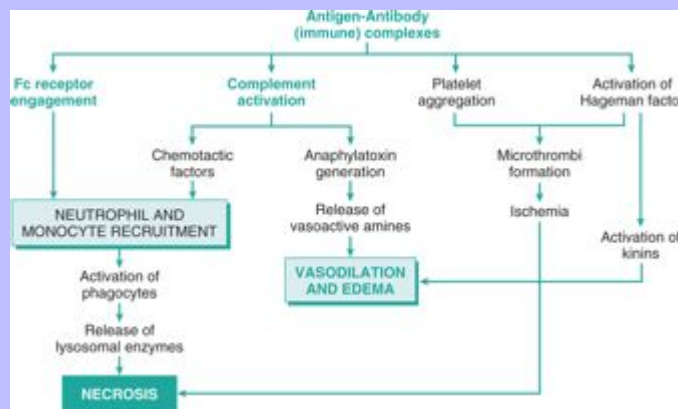

### TYPE IV HYPERSENSITIVITY (DELAYED-TYPE HYPERSENSITIVITY)

Type IV hypersensitivity is also known as cell-mediated hypersensitivity because it is the result of the interaction of T lymphocytes and the specific antigen to which they have been sensitized. The resulting immune response is mediated either by direct cytotoxicity by CD 8<sup>+</sup> T lymphocytes or by the release of soluble cytokines from CD 4<sup>+</sup> lymphocytes, which act through mediator cells (primarily macrophages) to produce chronic inflammatory reactions (Fig. 5-20). Because these responses are dependent on sensitized T lymphocytes and require 24 to 48 hours to develop, they are also referred to as delayed-type hypersensitivity (DTH). Unlike type I, II, and III hypersensitivity reactions, type IV hypersensitivity is not dependent on an antibody. We will first discuss the response mediated primarily by activated CD4<sup>+</sup> lymphocytes. The prototypical DTH reaction is the localized tuberculin response. Following an intradermal exposure of tuberculin, a purified protein derivative (PPD) of the tubercle bacillus, a previously sensitized host will develop a localized type IV reaction at the site of inoculation at 24 to 72 hours. The intradermal antigens are taken up and processed by dendritic Langerhans' cells, which present antigenic peptides to antigen-specific CD4<sup>+</sup> lymphocytes that are activated to produce and secrete cytokines that attract and activate other inflammatory cells. Grossly the site appears as a swollen, firm nodule. Microscopically the nodule is composed of interstitial edema and a mononuclear infiltrate that is primarily centered around blood vessels. Early (<12 hours), the infiltrate is primarily neutrophilic, which is replaced largely by macrophages and lymphocyte (>12 hours). The DTH response is generally minimal and short lived, as the concentration of PPD injected is small and rapidly degraded. A similar DTH reaction can be used to test for previous exposures to a number of intracellular organisms.

221

223

Fig. 5-19 **Pathogenesis of type III hypersensitivity reactions and the morphologic consequences.** Locally or systemically deposited immune complexes result in tissue damage and inflammation by activation of the complement system and through activation of neutrophils and macrophages through their Fc receptors. Activation of a component of the coagulation system also contributes to the tissue damage. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

**Fig. 5-20 The two primary mechanisms of T lymphocytes that cause type IV hypersensitivity reaction. A,  $CD4^+$  T lymphocytes (and occasionally  $CD8^+$  lymphocytes) are activated by antigen and produce cytokines that attract other cell types and promote an inflammatory response. B,  $CD8^+$  T lymphocytes (cytotoxic T lymphocytes [CTLs]) are also activated by antigen and can cause inflammation by killing targeted cells and tissue. APC, Antigen-presenting cell. (A and B, From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)**

In addition to the tuberculin response, type IV hypersensitivity is the underlying pathogenesis for allergic contact hypersensitivity and granulomatous inflammatory responses. As mentioned with the other hypersensitivity reactions, the components of a type IV hypersensitivity reaction can be considered beneficial (protective immunity) when they occur as an appropriate response to intracellular organisms, or they can be considered harmful (hypersensitivity), for example, when they occur as an inappropriate response to exogenous chemicals or substances that are complexed with proteins, as in the case of allergic contact hypersensitivity. Type IV hypersensitivity, also known as delayed-type hypersensitivity or cell-mediated hypersensitivity, occurs when sensitized T lymphocytes encounter antigens and are activated to produce cytokines that induce a cell-mediated immune response, which develops over a 24- to 72-hour period. The classic type IV reaction is the tuberculin response.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-10 Diseases with a Primary Type IV Hypersensitivity (Delayed-Type Hypersensitivity) Pathogenesis

Disease	Specificity of Pathogenic T Lymphocytes	Clinicopathologic Manifestations
Tuberculosis	<i>Mycobacteria</i> spp. antigens	Granuloma formation
Allergic contact dermatitis	Haptens	Perivascular dermatitis
Rheumatoid arthritis	Unknown antigen in joint synovium (type II collagen?); role of antibodies and type III hypersensitivity?	Chronic arthritis with inflammation, destruction of articular cartilage and bone
Johne's disease	<i>Mycobacterium paratuberculosis</i> antigens	Granulomatous enteritis
Allograft rejection	MHC molecules	Inflammation of graft tissue
Equine recurrent uveitis	Unknown	Uveitis

MHC, Major histocompatibility complex.

In the tuberculin reaction, the quantity of antigen limits the extent of the inflammatory response, and resolution of the inflammation generally occurs in 5 to 7 days. This is in contrast to chronic infections with persistent intracellular organisms or poorly degradable intracellular antigens (Table 5-10) that develop into a specific type of chronic inflammatory response called granulomatous inflammation. DTH reactions frequently occur in response to intracellular organisms and cause extensive tissue damage. These diseases are characterized by granulomatous inflammation. In this type of response, the host is unable to destroy or eliminate the organism, resulting in antigen persistence. Compared with the tuberculin reaction, the type of inflammatory infiltrate is different. As discussed in Chapter 4, granulomatous inflammation designates that the inflammatory infiltrate has specific attributes, notably the presence of morphologically transformed macrophages into epithelial-like cells commonly called epithelioid macrophages (Figs. 5-21 and 5-22). Concurrently, there may be many multinucleated giant cells that represent fused macrophages. A number of fusion-related monocyte-macrophage surface proteins have been identified and include receptors for mannose and  $\beta_1$  integrin, SHPS-1, and the chemoattractant chemokine ligand 2. Lymphocytes can also represent a significant component of the inflammatory infiltrate. Generally,  $CD4^+$  lymphocytes are interspersed with the macrophages, and  $CD8^+$  lymphocytes are localized to the periphery. As these lesions progress, they may become organized into nodules commonly called granulomas (Fig. 5-22). Depending on the inciting antigen, there may also be varying proportions of necrosis (often as a necrotic center), calcification of the necrotic tissue, and peripheral fibrous encapsulation. These features are largely the result of lytic enzymes released from activated macrophages. Nonimmunologic granulomas can occur in cases of foreign-body type granulomas, which typically have fewer lymphocytes. In either case, the body is trying to limit the spread or wall off the inciting antigen.

223

Note the partially encapsulated nodule composed of sheets of epithelioid macrophages and the central area of neutrophils. H&E stain. **B**, Mycobacteriosis, lung, gazelle. Numerous epithelioid macrophages and multinucleated giant cells (*arrows*) constitute the granulomatous tissue that has replaced normal lung parenchyma. H&E stain. (**A** and **B**, Courtesy Dr. P.W. Snyder, School of Veterinary Medicine, Purdue University.)

**Fig. 5-22 Schematic depiction of granuloma formation in a type IV hypersensitivity reaction.** A  $T_H1$  lymphocyte synthesizes cytokines in response to interleukin (*IL*)-12 production and antigen presentation by an antigen-presenting cell. The cytokines activate additional  $T_H1$  lymphocytes (*IL*-2) and monocyte-macrophage cells (interferon- $\gamma$  [*IFN*- $\gamma$ ]), and promote localized and systemic inflammatory responses (tumor necrosis factor [*TNF*]- $\alpha$ ). As the response develops, macrophages fuse to form multinucleated giant cells, and fibroblasts are stimulated to synthesize collagen, resulting in the formation of a granuloma. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

224

The type IV hypersensitivity reaction is immunologically specific and like all the hypersensitivity reactions involves a sensitization phase and an effector phase. The sensitization phase occurs with the initial exposure

---

to the antigen and results in the development of antigen-specific memory T lymphocytes. These  $CD4^+$  lymphocytes recognize peptides presented in the context of class II molecules on the surface of antigen-presenting cells. In this context, the naïve  $CD4^+$  T lymphocytes develop into functional  $T_H1$  lymphocytes. These activated  $T_H1$  lymphocytes are sometimes designated as  $T_{DTH}$  lymphocytes. Once the host is sensitized, a prolonged exposure or repeat exposure to the antigen results in the development of an effector phase. The effector phase can occur as a cytotoxic response mediated by  $CD8^+$  lymphocytes or more commonly as a  $T_H1$  response through the elaboration of cytokines by  $CD4^+$  lymphocytes (Fig. 5-22).  $T_H1$  cytokines (most importantly, IL-2, IL-3, IFN- $\gamma$  and TNF- $\beta$ ) and chemokines (IL-8, macrophage chemotactic and activating factor, and macrophage-inhibition factor) enhance the function of cytokine-producing T lymphocytes (autocrine and paracrine fashion) and attract and activate macrophages. IL-2 induces the proliferation and long-term survival of T lymphocytes. IL-3 supports the growth and differentiation of  $T_H1$  lymphocytes and NK cells. IFN- $\gamma$ , the key mediator of type IV hypersensitivity, activates macrophages not only to enhance their phagocytic and killing mechanisms but also to enhance their ability to present antigen by inducing increased expression of class II MHC molecules. Activated macrophages and dendritic cells produce IL-12, which also facilitates the development of  $T_H1$  lymphocytes. Activated macrophages also produce IL-1 and TNF- $\alpha$ , both of which act locally to increase the expression of adhesion molecules on endothelial cells, which further facilitates the extravasation of additional inflammatory cells. The production of cytokines and chemokines by the  $CD4^+$   $T_H1$  lymphocytes influences macrophage function and mediates the production of cytokines that influence  $CD4^+$  lymphocytes, resulting in a response that potentially goes from a beneficial protective response (immunity) to a harmful response that results in tissue damage (hypersensitivity).

The beneficial protective response of T lymphocyte-mediated hypersensitivity is not limited to intracellular organisms. It also can be a primary component of transplant rejection and immunity to cancer. There are other harmful T lymphocyte-mediated responses that result in disease. One example is allergic contact hypersensitivity. In allergic contact hypersensitivity, the antigen is often too small to elicit an immune response by itself. These antigens must be complexed with other, larger proteins to become antigenic and are specifically referred to as haptens or generally called contact antigens (Box 5-1). Allergic contact hypersensitivity is also dependent on processing and presentation of the antigen by dendritic Langerhans' cells to  $CD4^+$  lymphocytes in regional lymph nodes. In the case of allergic contact dermatitis, the keratinocyte may also participate by producing a number of cytokines that activate Langerhans' cells, mast cells, and other inflammatory cells. In the sensitization phase, the protein-hapten complex is taken up and processed by Langerhans' cells that migrate to regional lymph nodes. In the paracortex region of the lymph node (T-lymphocyte area), they present antigenic components to  $CD4^+$  lymphocytes. The host develops a population of memory cells and is now sensitized to the antigen. In a sensitized host, continuous exposure to the antigen, or more commonly repeat exposure to the antigen, results in an effector phase response seen as epidermal vesicle formation with dermal and epidermal infiltrates of mononuclear inflammatory cells. The result is tissue damage that is disproportionate to any beneficial effects of the immune response.

Finally, as mentioned earlier, another form of DTH can occur that is mediated by direct cytotoxicity by CD 8<sup>+</sup> T lymphocytes. This response is most commonly associated with viral infections. CD 8<sup>+</sup> T lymphocytes, bearing viral antigen-specific TCRs, kill antigen-expressing target cells. These cells are commonly referred to as cytotoxic T lymphocytes (CTLs). The expression of viral proteins on the surface of an infected cell in association of class I MHC molecules serves as the recognition signal for the TCR-CD3 membrane complex. Following recognition of antigen by the CTL, there is up-regulation of adhesion molecules on the CTL and the target cell, resulting in a CTL–target cell conjugate. This stimulates an activating signal pathway that results in death of the target cell by apoptosis. The two principal mechanisms of CTL-mediated apoptosis are: (1) the directional delivery of cytotoxic proteins, and (2) the interaction of membrane-bound Fas ligand on the CTL, with the Fas receptor on the target cell. Both are dependent on the activation of caspases. Perforins and granzymes are preformed cytotoxic proteins contained in the cytoplasmic granules of CTLs. Perforin, released between the conjugated CTL and the target cell, is polymerized in the presence of Ca<sup>2+</sup> and forms pores in the plasma membrane of the target cell, not only causing lysis but also permitting the delivery of granzymes. Granzymes activate caspases, normally present in an inactive proenzyme form, that ultimately result in apoptotic death of the cell. The cross-linking of Fas by its ligand, membrane-bound Fas ligand, results in the activation of the extrinsic (death-receptor–initiated) pathway of apoptosis covered in greater detail in [Chapter 1](#).

### 5.4.2 CYTOKINE-RELATED DISEASES

A number of diseases are characterized by severe disruptions, either overproduction or underproduction, of cytokines or cytokine receptors. One of the most profound examples is the excessive elaboration of cytokines during bacterial septicemia and shock. The basic pathogenesis involves an infection with a gram-negative, endotoxin producing bacterium that stimulates macrophages to overproduce IL-1 and TNF- $\alpha$ . High concentrations of these two cytokines in circulation cause septic shock (see [Chapter 2](#)). A number of microbial

## Pathologic Basis of Veterinary Disease, 4th Edition

pathogens also produce toxins or other antigenic molecules that are referred to as superantigens. Superantigens bind to class II MHC molecules and  $V_\beta$  domains of the T-lymphocyte antigen receptor (TCR). This binding is outside the normal antigen binding site and activates all T lymphocytes expressing the same  $V_\beta$  domains, irrespective of their antigen specificity (Fig. 5-23). The result is the activation of numerous T lymphocytes (between 5% and 20% versus a normal response of <0.01%) and the elaboration of cytokines. Superantigens are subclassified as exogenous or endogenous. Exogenous superantigens are produced by bacteria and include some enterotoxins, exfoliating toxin, and toxic shock syndrome toxin (TSST1). Endogenous superantigens are specific cell-membrane molecules produced during viral infections of cells. The best characterized is minor lymphocyte stimulating (Mls) determinants associated with mouse mammary tumor virus infections. Similar to bacterial septic shock, increased serum concentrations of IL-1 and TNF- $\alpha$ , cause systemic responses like fever, disseminated intravascular coagulation (DIC), and shock.

### 5.4.3 TRANSPLANT REJECTION

Immunologic responses are responsible for transplant rejection, and some of the basic features of those responses are discussed here. Although the frequency and success of transplantation of tissues in humans is increasing, the frequency and success in domestic species remains very low. Most of the literature on domestic species is related to the development and characterization of animal models rather than as a form of medical treatment. The most common tissue transplants in veterinary medicine are kidney grafts in dogs and cats with end-stage renal disease. The most common graft is an allograft, defined as a graft between two individuals of the same species. Graft rejection largely occurs as a result of the recipient recognizing the grafted tissue as foreign. The antigens responsible are the MHC molecules and blood group antigens of the graft. As discussed previously, MHC molecules are widely distributed and function as specialized molecules involved in intercellular recognition and the differentiation of self and nonself. Blood group antigens in domestic species are far more complex than those in humans. Transplant rejection is a complex process that involves both cell-mediated immunity and humoral immunity.

226

227

**Fig. 5-24 Schematic depiction of the two primary pathways of graft rejection.** The direct pathway is mediated by antigen-presenting cells within the graft recognizing major histocompatibility complex (MHC) molecules of the recipient and are recognized by CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes. The indirect pathway is mediated by graft antigens presented by antigen-presenting cells of the recipient that activate CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes, resulting in a type IV hypersensitivity reaction, CTLs, Cytotoxic T lymphocytes; IFN- $\gamma$ , interferon- $\gamma$ . (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

As we have discussed throughout this chapter, the cell-mediated immune response is primarily composed of two mechanisms that are mediated by T lymphocytes. Both mechanisms are involved in graft rejection (Fig. 5-24). The first mechanism, referred to as the direct pathway of graft rejection, is mediated by CD8<sup>+</sup> cytotoxic T lymphocytes (CTLs). In this instance the recipient's CTLs recognize allogenic MHC molecules expressed by antigen-presenting cells within the graft (donor origin). The molecular basis for the recognition signals are complex and poorly understood. The second mechanism, referred to as the indirect pathway of graft rejection, is mediated by the recipient's T lymphocytes that recognize antigens of the graft presented by the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

antigen-presenting cells of the recipient. In this mechanism the uptake of antigen (recipient MHC molecules), processing, and presentation to CD4<sup>+</sup> cells is identical as for any other foreign peptide, as we have discussed previously. However, in this instance the CTLs generated cannot directly kill graft cells because they are only recognizing graft antigens presented by the recipient's antigen-presenting cells. The indirect pathway is dependent on the activation of CD4<sup>+</sup> lymphocytes and the elaboration of cytokines and development of a DTH reaction. These activated CD4<sup>+</sup> cells also function to facilitate the development of an antibody (humoral) response against alloantigens in the graft. Generally graft rejection reactions are classified based on the pathologic findings within the rejected tissue as hyperacute, acute, and chronic. The human classification scheme for grading rejected renal transplants has been applied to feline renal transplant rejection reactions and was found to be less reliable in accurately characterizing the severity of the rejection reaction.

### 5.4.4 AUTOIMMUNE DISEASE

Autoimmunity is by definition a specific immune response to self-antigens. Autoimmunity reflects a loss of immunologic tolerance to self-tissue or cellular antigens and is characterized by abnormal or excessive activity of self-reactive immune effector cells. Autoimmunity can be organ specific, localized, or systemic. Autoimmunity can be mediated by both autoantibodies and by self-reactive T lymphocytes. The etiology of most autoimmune diseases remains elusive, as they are often multi-factorial and have a genetic and an environmental component. Criteria for diagnosing an autoimmune disease may include: (1) direct proof such as the fact that the disease can be transferred through cells or autoantibodies; (2) indirect proof as in identifying the antigen, then isolating the homologous antigen in an animal model, and reproducing the disease through administration of the antigen; (3) isolating self-reactive antibodies or T lymphocytes; and (4) circumstantial evidence such as familial occurrence, lymphocyte infiltrate, MHC associations, and clinical improvement with immunosuppressive therapy. The complexity of autoimmune diseases is also supported by the fact that nonpathologic autoreactive T lymphocytes and antibodies can be found in normal individuals. Most autoimmune diseases have a tendency to be characterized by cyclical periods of alternating clinical disease and convalescence, an increased susceptibility of the female sex, and a predisposition to multiple autoimmune phenomena as in the case of the mixed connective tissue disorders.

How does a loss of self-tolerance occur? In order to understand the mechanisms related to a loss of self-tolerance, one must first understand the basic concepts of maintaining immunologic tolerance to self-antigens.

#### 5.4.4.1 IMMUNOLOGIC TOLERANCE

When exposed to an antigen, the immune system can be responsive and develop an immune response or it can be nonresponsive and develop a state of tolerance. In either case, responsive or nonresponsive, the reaction is immunologically specific and has to be carefully regulated, as a response to a self-antigen or a nonresponse to a pathogen could be equally detrimental. Immunologic tolerance is an active physiologic process and is not simply the lack of an immune response. Immunologic tolerance is defined as a failure of the immune system to respond to a specific antigen after previous exposure to that antigen. It is an absence of a functional response rather than a lack of any response at all. The development of autoimmunity can be simply described as an escape from the mechanism by which self-tolerance is maintained.

Tolerance is maintained by a number of mechanisms including deletion, anergy, and suppression. Deletion, also referred to as self-tolerance, is the process of clonally eliminating self-reactive lymphocytes. For T lymphocytes, self-tolerance occurs as a developmental process of immature lymphocytes in the thymus,

## Pathologic Basis of Veterinary Disease, 4th Edition

---

termed central tolerance, and as a component of mature effector cells upon exposure to antigens in the peripheral tissues, known as peripheral tolerance (Fig. 5-25). Although immature B lymphocytes undergo selection processes in the bone marrow, independent of antigen, these are not referred to as central tolerance. Not all self-reactive B and T lymphocytes are deleted during their development. However, there are mechanisms of anergy and suppression that prevent the activation of self-reactive T or B lymphocytes outside the thymus and bone marrow.

5.4.4.1.1

### Central Tolerance

Central tolerance occurs during T lymphocyte development in the thymus, where self-reactive T lymphocytes are clonally eliminated. Central tolerance has been most extensively studied in the thymus (Fig. 5-25), where developing T lymphocytes undergo two selection processes that are essential for their development into mature effector cells and are based on the ability of developing lymphocytes to recognize self-peptides in association with MHC molecules. Positive selection is the clonal expansion of those cells capable of self-MHC restriction. Negative selection is the clonal deletion of those cells expressing TCRs capable of recognizing self-antigens in association with MHC molecules. Developing T and B lymphocytes expressing high avidity receptors for self-antigens are deleted from further development, resulting in a peripheral effector cell population lacking self-reactive cells. Self-reactive lymphocytes are eliminated by an apoptotic mechanism. For T lymphocytes, it is the interaction of an immature lymphocyte and an antigen-presenting cell that triggers the process of clonal deletion of self-reactive T lymphocytes. This process of clonal deletion involves an apoptotic pathway mediated by the Fas-Fas ligand. The exact molecular signals that trigger this apoptotic pathway remain elusive. The expression of peripheral antigens in the thymus is thought to be partially mediated by a protein called AIRE (autoimmune regulator), which is thought to be essential for the deletion of immature self-reactive T lymphocytes. Negative selection for developing B lymphocytes also occurs through a clonal deletion process involving an apoptotic pathway for those cells that have “excessive” stimulation of their antigen receptor molecules during development. Although the mechanisms regulating tolerance during lymphocyte development are very effective at identifying and eliminating self-reactive T and B lymphocytes, they are not perfect, as self-reactive lymphocytes can be identified in normal individuals. Lastly, the development of central tolerance requires exposure to the antigen during lymphocyte development, and many self-antigens are not present in the thymus or bone marrow. These self-antigens are commonly referred to as sequestered antigens because they are not seen by the developing lymphocytes. Some of the tissue antigens that fall into this class of antigens include: myelin basic protein, lens proteins, and sperm, to mention a few. These antigens can be released as a result of infection or trauma and result in an immunologic response by self-reactive lymphocytes against myelin, lens, and sperm, respectively.

**Fig. 5-25 Central and peripheral tolerance.** Schematic illustration of the mechanisms of central and peripheral tolerance of T lymphocytes. APC, Antigen-presenting cell, *FasL*, Fas ligand; *MHC*, major histocompatibility complex. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Because the development of self-reactive lymphocytes may escape the mechanisms of central tolerance, the immune system has developed peripheral tolerance mechanisms to prevent these cells from becoming activated and developing into effector cells capable of causing autoimmunity.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

5.4.4.1.2

### Peripheral Tolerance

In peripheral tolerance, self-reactive T lymphocytes that are not eliminated as a result of negative selection processes in the thymus have the potential to cause tissue injury when they exit the thymus and enter the peripheral tissues. Within the peripheral tissues there are mechanisms to prevent the activation of these self-reactive lymphocytes, and these occur as a consequence of the normal immune response to antigen and involve the same signals required for activation of lymphocytes during an immune response. Regulation of cellular activation occurs primarily by three mechanisms, which are briefly discussed next.

5.4.4.1.2.1

### Anergy

Anergy is the functional inactivation of lymphocytes that encounter antigen. As previously discussed, two signals are required for the activation of naïve T lymphocytes by antigen-presenting cells. The first is generated by interaction of peptide antigen in association with MHC molecules on the surface of antigen-presenting cells within the TCR-CD3 complex, and the second is generated by the presence of co-stimulatory molecules. Co-stimulatory molecules are essential for the activation of naïve T lymphocytes and involve the interaction between T lymphocyte molecules (CD28) and their ligands (B7-1 and B7-2) on antigen-presenting cells. The interaction of CD28 with B7 results in T-cell activation and its survival. However, if an antigen-presenting cell does not provide the co-stimulatory signal, the T lymphocyte receives a negative signal, and the cell becomes anergic ([Fig. 5-25](#)). Another mechanism for inducing anergy involves the delivery of a specific inhibitory signal by CTLA-4 molecules on T lymphocytes that also bind to B7 molecules. The interaction of CTLA-4 with B7 results in inhibition of activation by blocking IL-2 production. The process of anergy is irreversible. The limited expression of co-stimulatory molecules by normal tissue facilitates the maintenance of peripheral tolerance to self-reactive lymphocytes. In general, CD 28 is expressed on resting and activated T lymphocytes, whereas CTLA-4 is only expressed on activated T lymphocytes. What drives a T lymphocyte, expressing CD 28 molecules, to recognize B7 molecules that lead to activation or to express CTLA-4 molecules that recognize the same B7 molecules that leads to anergy is unknown. Anergy of B lymphocytes occurs largely through the absence of specific T-helper cell activation, although negative selection of mature self-reactive B lymphocytes is known to occur. An inability of B lymphocytes to receive appropriate signals from T-helper lymphocytes, subsequent to antigen exposure, results in their deletion from lymphoid tissues.

5.4.4.1.2.2

### Suppression by regulatory T lymphocytes

This mechanism of peripheral tolerance occurs through the activation of regulatory cells that prevent immune reactions to self-antigens. Suppression can occur as a result of cross-regulation of  $CD4^{+} T_H1$  cells by a specific population of  $CD4^{+} T_H2$  cells. Specifically,  $CD25^{+}$  and  $CD4^{+} T_H2$  cells producing IL-4, IL-10, and TGF- $\beta$  down-regulate  $T_H1$  responses, effectively inhibiting lymphocyte activation and its effector function.

5.4.4.1.2.3

### Clonal deletion by activation-induced cell death

As discussed previously, one of the possible outcomes following lymphocyte activation as a result of antigen recognition during an immune response is lymphocyte proliferation. A second possible out

## Pathologic Basis of Veterinary Disease, 4th Edition

come following antigen exposure is cell death. For CD4<sup>+</sup> T lymphocytes, both outcomes—proliferation and death—are largely regulated by the expression of accessory co-stimulatory molecules.

230

Activation-induced cell death (AICD) of T lymphocytes occurs by Fas-Fas ligand signaling following persistent stimulation by antigen-presenting cells expressing antigen. During the normal immune response, AICD functions to down-regulate immune responses and results in the return to immune homeostasis. Lymphocytes can be induced to express Fas (CD95), a member of the TNF-receptor family. The ligand for Fas, Fas ligand (FasL), is expressed primarily on activated T lymphocytes. The binding of Fas to FasL results in apoptosis of activated T lymphocytes. Antigens that are expressed to a high level in normal tissue would result in persistent stimulation of self-reactive T lymphocytes, thus resulting in deletion through Fas-FasL-mediated apoptosis. In the case of an autoreactive B lymphocyte exposed to soluble antigen in the periphery, the cell becomes anergic. If the anergic autoreactive B lymphocyte is recognized by a T lymphocyte specific for the autoantigen, the interaction of the Fas ligand on the T lymphocyte binding to the Fas molecule on the B lymphocyte results in activation-induced cell death of the B lymphocyte. Two strains of mice have been identified with a mutation in either the Fas molecule (lpr mice) or the FasL (gld mice). The lpr and gld strains have severe autoimmune disease develop with a phenotype similar to that of humans with systemic lupus erythematosus (SLE).

231

### 5.4.4.1.2.4

#### Antigen sequestration

Antigens that are not expressed in the thymus or are “cryptic” in nature have the potential to induce a self-reactive immune response. Certain physiologic characteristics of some tissue (e.g., testis, eye, and brain) are considered to render them as “immunologically privileged sites” because of the difficulty in eliciting an immune response to antigens in these tissue. Antigens in these sites cannot be seen by the immune system because they are sequestered. The sequestering of antigens may occur through the blood-brain barrier, an absence of lymphatic drainage, or the limited ability to express MHC molecules. A mechanism for the eye is referred to as the anterior chamber-associated immune deviation (ACAID), thought, in part, to be the result of inhibitory cytokines, such as TGF- $\beta$ , produced by the cells of the iris and ciliary body. However, if the antigens in these tissues are released as the result of trauma or infection, they have the potential to cause a severe immune response as a consequence of activating self-reactive lymphocytes. Posttraumatic uveitis and orchitis are thought to be the result of the release of sequestered antigens.

### 5.4.5

#### MECHANISMS OF AUTOIMMUNITY

Although central tolerance is important in lymphocyte development, it is the mechanisms of peripheral tolerance that have a greater influence on the development of autoimmunity. We have described the complexities of central and peripheral tolerance, and thus it is understandable that the mechanisms responsible for allowing autoreactive lymphocytes to become activated and develop into self-reactive T lymphocytes or autoantibody-producing plasma cells are equally diverse and complex (Fig. 5-26). Although autoantigens have been described for a number of autoimmune diseases, it is the identification of the initiating antigen that remains elusive. The cause of most autoimmune diseases remains unknown, as they often are multifactorial and have genetic and environmental components (Fig. 5-27).

### 5.4.5.1 FAILURE OF PERIPHERAL TOLERANCE

Previously we discussed the mechanisms self-tolerance, which will now serve as a basis for presenting how a failure to maintain those mechanisms can contribute to the pathogenesis of autoimmunity.

### 5.4.5.2 GENETIC FACTORS IN AUTOIMMUNITY

The majority of autoimmune diseases in humans have a strong genetic predisposition. The most well-studied genetic component centers around the MHC molecules. As previously discussed, MHC molecules are important in the development of lymphocytes and in the regulation of peripheral effector lymphocytes. Just as autoreactive lymphocytes have been identified in normal individuals without autoimmune disease, the presence of certain MHC molecules themselves is not sufficient to result in autoimmune disease. These observations would suggest that the expression of an autoimmune phenotype is not likely to be the result of a single-gene defect. Other genes that regulate proteins involved in other aspects of the immune response, or that are involved in the inflammatory or healing response, may also be involved. Additionally, experimental variations in the expression and activity of transcription factors can influence the expression of certain autoimmune diseases.

Several strains of mice with specific genetic mutations of factors involved in the maintenance of central and peripheral tolerance that results in autoimmune disease have been identified. Mice with defects of Fas or FasL have disruption of the activation-induced cell death signal in lymphocytes, resulting in autoimmune disease. Mice lacking the transcriptional factor AIRE, which is responsible for thymic expression of self-antigens, and mice defective in the expression of CTLA-4, the inhibitory receptor involved in T-lymphocyte anergy, also develop autoimmunity. An important regulatory cytokine—IL-2, the major growth factor for lymphocytes—is also required for the development and function of regulatory T lymphocytes. Mice lacking either IL-2 or the IL-2 receptor develop autoimmune disease characterized by inflammatory bowel disease, anti-DNA antibodies, and autoimmune hemolytic anemia. The proposed mechanism of autoimmunity in these mice is thought to involve T lymphocytes and be a result of a failure of suppression by regulatory T lymphocytes and a failure of activation induced cell death, two mechanisms of peripheral tolerance. These mouse models of autoimmune disease have facilitated the identification of pathogenic mechanisms of autoimmunity. Although all of these mechanisms have now been identified in human autoimmune diseases, it is likely only a matter of time before they are identified in other species.

231

233

(From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Of the domestic species, there have been a number of autoimmune diseases in dogs documented to have a familial tendency, and the mechanism is in part attributed to certain MHC alleles. These recognized associations of specific autoimmune diseases and MHC molecules have been limited to a few specific breeds. It should also be noted that other diseases of immunity, for example, immunodeficiency and atopy, also have a higher incidence in some breeds.

### 5.4.5.3

#### MICROBIAL AGENTS IN AUTOIMMUNITY

The recognition that certain infections may result in the development of an autoimmune disease is the result of two observations. First, experimentally, one can induce autoimmunity in specific strains of mice by infection with certain strains of virus. Second, many spontaneous autoimmune diseases occur following viral infections, although attempts to isolate and identify viral agents in patients with autoimmune diseases have been equivocal. Again, these observations would suggest that these diseases have a complex pathogenesis with a genetic and an environmental component.

The role of infections as environmental factors in the pathogenesis of autoimmune diseases may be explained by understanding how infectious agents may cause a break down of anergy to self-molecules (loss of self-tolerance). As discussed earlier, not all self-reacting B and T lymphocytes are eliminated during the differentiation and development process. These potentially self-reacting lymphocytes are regulated in the periphery by clonal anergy. Therefore a loss of this regulation could explain how autoimmune diseases

## Pathologic Basis of Veterinary Disease, 4th Edition

develop. Plausible mechanisms of why infectious agents cause aberrations of peripheral clonal anergy are twofold (Fig. 5-28). One mechanism may be the result of nonspecific disruption of the regulatory cells, which results in the induction of co-stimulatory molecules on antigen-presenting cells that are expressing self-molecules. This mechanism is not specific to the antigens of the infectious agent and is likely the result of the overall inflammatory response to the pathogen. Additionally, during an inflammatory response, some cells are induced by the inflammatory cytokine IFN- $\gamma$  to increase their expression of MHC molecules. This can result in the expression of MHC molecules by cells that normally do not express them. Although the expression of MHC molecules in the absence of co-stimulatory molecules will not activate T lymphocytes, it does increase the potential to do so if co-stimulatory molecules are inappropriately expressed. The second mechanism is specific to the antigens of the infectious agent and is the result of cross-reactivity of T lymphocytes with an infectious agent's antigen and a self-antigen. Many infectious agents express antigens that have similar peptide sequences to those of normal peptides as a part of their immune evasion mechanism. Therefore the potential exists for any immune response to an infectious agent to cross-react with a normal peptide, resulting in an immune response directed against self-cells or self-tissues. This mechanism is called molecular mimicry. The result is the activation of T lymphocytes that recognize the infectious agent peptide-MHC complex. These T lymphocytes can potentially attack self-peptide-MHC complexes that are cross-reactive.

Once an autoimmune disease is initiated, the clinical course is generally progressive and characterized by cyclical periods of exacerbation and remission. As with any immune-mediated disease, antigen persistence is required to maintain the functional immune response. In autoimmune diseases, antigen persistence is thought in part to occur through epitope spreading. Epitope spreading is the process by which the immune response spreads from one epitope of an antigenic molecule to another, non-cross-reacting, epitope of the same antigenic molecule, or from one epitope of different peptides that are a part of a large complex. The epitopes involved are frequently ones that the immune response has not developed tolerance against because they are not normally presented by MHC molecules in sufficient concentrations. These so-called cryptic epitopes are normally not expressed at sufficient concentrations or are "hidden" during differentiation and development of lymphocytes. However, during an infection or inflammatory response, there may be tissue or cell damage that results in the release or expression of cryptic or hidden epitopes of self-antigens, and these become targets for the immune response. Because these epitopes were hidden, the immune system has not developed tolerance to them. Epitope spreading is thought to maintain the initiated immune response by means of the continued recruitment of autoreactive T lymphocytes specific for normal "cryptic" self-peptides.

233

234

**Fig. 5-28 Autoimmunity and the role of infections in its pathogenesis.** APC, Antigen-presenting cell. (From Kumar V, Abbas AK, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

With this basic understanding of self-tolerance, and the possible molecular mechanisms involved in the pathogenesis of autoimmunity, we can present some of the more common autoimmune diseases of domestic species. Autoimmune diseases can be organ specific or systemic. With many of the organ-specific diseases, an immunologically mediated pathogenesis is suspected because of the finding of a lymphocytic inflammatory reaction within the affected tissue. Rarely, autoantibodies may be identified in the circulation. The organ-specific autoimmune diseases are discussed in the appropriate chapters covering individual organ systems. This chapter will focus on some of the systemic autoimmune diseases of domestic species, beginning with the multisystemic disease systemic lupus erythematosus.

### 5.4.6 SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is one of the most well-studied systemic autoimmune diseases in humans and is characterized by the production of autoantibodies directed against a wide array of normal tissue and cellular components. The predominant autoantibody, commonly known as antinuclear antibody (ANA), is directed against nuclear antigens. The disease has been described in humans, nonhuman primates, mice, horses, dogs, cats, snakes, and iguanas. As with many autoimmune diseases, SLE has a highly variable and often progressive clinical course characterized by a variety of clinical and immunologic abnormalities. Unlike humans, in whom the disease predominantly affects women, there is no clear sex predilection in domestic species. There are certain breeds of dogs that have a higher incidence. The average age of diagnosis is approximately 5 years. Epidemiologic data on other species is limited.

234

#### 5.4.6.1 ETIOLOGY AND PATHOGENESIS

235

The cause of SLE remains undetermined, although the presence of autoantibodies directed against a number of tissues and cellular components suggests that the underlying immunologic abnormality is a failure to maintain self-tolerance. Antibodies against nuclear and cytoplasmic components, which are neither organ specific or species specific, and those directed against cell surface antigens, particularly red blood cell antigens, are central to the pathogenesis of the disease. Detection of autoantibodies also facilitates the diagnosis and monitoring of human patients with SLE. The autoantibodies and self-antigens form immune complexes, which can be deposited in glomeruli (glomerulonephritis), blood vessels (vasculitis), skin (dermatitis), and joints (arthritis), resulting in the major clinical signs associated with the disease.

Antinuclear antibodies are found in a high percentage of patients with SLE. In humans, antinuclear antibodies are grouped into four categories: (1) antibodies against DNA, (2) antibodies against histones, (3) antibodies to nonhistone proteins bound to RNA, and (4) antibodies against nucleolar antigens. The most common method of measuring antinuclear antibodies is indirect immunofluorescence. The pattern of immunofluorescence is used to help identify the type of autoantibody present. Other methods can be used to more specifically identify the target of ANA. In human beings, the majority of ANAs are directed against nucleic acids in native double-stranded DNA, in contrast to the dog, in which the majority of ANAs are directed against nuclear proteins such as histones and extractable nuclear antigens (ENAs). ANAs are also found in normal patients and in patients with other diseases; however, their frequency is much lower. In the dog, the incidence of ANA in normal dogs and dogs with other canine diseases is 16% and 20%, respectively, compared with 97% to 100% in dogs with SLE. The indirect immunofluorescence test for ANA is sensitive but not specific because of the relatively high incidence in normal dogs and those with non-SLE diseases. Two anti-ENA antibodies appear to be specific for canine SLE. These are the anti-Sm and the anti-T1 antibodies.

## Pathologic Basis of Veterinary Disease, 4th Edition

Patients with SLE frequently have autoantibodies in an array of tissue and cells. Many patients have rheumatoid factors and thus have a positive Coombs' test for anti-IgG antibodies. Antibodies directed against cellular antigens on red blood cells, platelets, and lymphocytes are frequently noted. In these instances they may lead to clinical signs of hemolytic anemia (anti-RBC antibodies), thrombocytopenia (anti-platelet antibodies), and immune system abnormalities (anti-lymphocyte antibodies). Other autoantibodies to components of muscle (myositis) and skin (dermatitis) are also frequently detected. While there can be an extensive number of autoantibodies identified in patients with SLE, the major clinical signs are attributed to the deposition of immune complexes in the joint, skin, and kidney and the elaboration of a type III hypersensitivity reaction. The tissues most frequently involved are in the joint, skin, and kidney.

Canine lupus primarily affects middle-aged dogs and in some studies has been reported to occur more frequently in males than females. Breeds overrepresented are the Shetland sheepdog, German shepherd, Old English sheepdog, Afghan hound, beagle, Irish setter, and poodle. Affected dogs usually present with a spectrum of clinical signs and the disease has a progressive clinical course. Common clinical findings include fever, nonerosive polyarthritis, glomerulonephritis, mucocutaneous lesions, lymph node and splenic enlargement, and hematologic abnormalities (e.g., anemia, thrombocytopenia, and leukopenia). ANAs are the most common immunologic finding. In some reports, up to 100% of affected animals have been positive for ANAs. Dogs can also have anterythrocyte antibodies (Coombs' positive), anti-IgG antibodies (rheumatoid factor positive), circulating immune complexes and deposits of these in the skin. Only the direct Coombs' test is valid in the dog. In the dog, as in other species, the immunologic abnormalities involve both humoral and cellular immunity. The abnormalities in humoral immunity are largely attributed to the already discussed presence of autoantibodies and are centered on the activation of self-reactive B lymphocytes. The abnormalities in cellular immunity include a lymphopenia that is characterized by a decrease in the percentage and absolute number of CD8<sup>+</sup> lymphocytes and a concurrent increase in the percentage and a decrease in the absolute number of CD4<sup>+</sup> lymphocytes. This translates into a high CD4<sup>+</sup>:CD8<sup>+</sup> ratio (as high as 6 in dogs with SLE versus <2 in normal dogs).

### 5.4.6.2

#### LESIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

A wide spectrum of morphologic lesions is associated with canine SLE. The most common finding, polyarthritis, is characterized as a nonerosive lesion that commonly affects the intervertebral, carpal, tarsal, and temporomandibular joints. The acute arthritis is characterized by exudation of neutrophils and fibrin into the synovial membrane and concurrent perivascular cuffing by mononuclear cells. The primary differential diagnosis for the arthritis is rheumatoid arthritis, which is an erosive lesion. The renal lesion, the result of immune complex deposition, involves the glomerulus, blood vessels, and the basement membranes of renal tubules (Fig. 5-29). The resulting glomerulonephritis is variable in appearance and ranges from slight mesangial alterations to diffuse proliferative lesions. The renal lesions have a common pathogenic mechanism that is a result of the deposition of immune complexes and the activation of complement (type III hypersensitivity). Glomerular lesions are often indicated by a persistent proteinuria (>0.5 g/dL).

235

236

**Fig. 5-29 Immune-complex glomerulonephritis, Aleutian mink disease, kidney, glomerulus, mink.** Intraglomerular immunoglobulin deposits demonstrated by immunofluorescence. Note the granular (“lumpy-bumpy”) pattern of fluorescence in this case of Aleutian mink disease. Immunofluorescence microscopy. (Courtesy Dr. S.J. Newman, College of Veterinary Medicine, University of Tennessee.)

Skin lesions are highly variable and nonspecific in canine SLE. The face, ears, and digital extremities are frequently involved and characterized by erythema, ulceration, and exfoliative dermatitis. The distribution of the lesions suggests that photosensitization may play a role. Histologically, the epidermis is characterized by basal cell vacuolation and necrosis, and the dermis is variably edematous with a superficial infiltration of mononuclear inflammatory cells at the dermal-epidermal junction (interface dermatitis). Additionally, there may be a panniculitis, composed primarily of lymphocytes and plasma cells, and vasculitis, with fibrinoid necrosis of the vessel wall. By indirect immunofluorescence, there are deposits of immunoglobulin and complement components at the dermal-epidermal junction. Other dermatologic variants of lupus are covered in [Chapter 17](#). The definitive diagnosis of SLE is based on accepted criteria rather than pathognomonic findings. Using 11 established criteria for the dog, modified from the American Rheumatism Association criteria for humans, a definitive diagnosis requires the presence of four or more criteria. A “probable” diagnosis is based on the presence of three criteria or the presence of polyarthritis with the identification ANAs. Other diagnostic schemes, using “major” and “minor” signs along with a positive ANA or SLE prep test, are also used to make definitive and probable diagnoses.

In the cat, SLE is less well recognized and manifests with fever, glomerulonephritis, dermatitis, and hemolytic anemia. The ANA test in cats is less reliable because many normal cats can have positive test results. Horses with SLE similarly present with generalized skin disease and may also have glomerulonephritis, arthritis, and hemolytic anemia.

5.4.6.3

### GENETIC FACTORS

SLE in humans is characterized as a disease with a complex genetic component with MHC and multiple non-MHC genes involved. Extensive genetic studies in domestic animals are lacking, yet it is reasonable to suggest that the disease in other species will also be characterized by involvement of multiple genes. The association of SLE with certain MHC alleles in human beings indicates that the MHC genes that regulate the production of specific antibodies are involved—specifically, MHC alleles that are linked to the production of anti-double-stranded DNA, anti-Sm, and antiphospholipid antibodies. Other than the observation of breed predilections for the dog and cat and the report of an association with the canine MHC allele DLA-A7, there are no definitive genetic studies similar to those reported in humans. Interestingly a low percentage of humans with SLE also have inherited deficiencies of complement components, such as C2, C4, or C1q. Because complement components are important in the removal of circulating immune complexes by the monocyte-macrophage system, such a deficiency may contribute to the deposition of circulating complexes into tissue rather than to their removal. There is an increase in lupuslike autoimmunity in mice lacking certain complement components. Finally a well-described animal model of SLE is the NZB × NZW mouse strain, in which a number of genetic loci have been identified as being associated with the development of the disease.

5.4.6.4

### ENVIRONMENTAL FACTORS

In addition to the genetic factors, SLE in humans has also been associated with a number of environmental factors. Specifically, drugs such as hydralazine, procainamide, and D-penicillamine can induce an SLE-like disease. In domestic animals, exposure to specific drugs and viral infections are suspected. Exposure to ultraviolet light is known to exacerbate the disease in the dog. These patients present with dermatologic manifestations localized to areas exposed to sunlight (e.g., face and dorsal regions) or areas lacking adequate hair coat (e.g., axillary region). A similar association has been noted in humans with SLE. The influence of UV radiation may be attributed to tissue damage and inflammation that result in activation of keratinocytes and the elaboration of IL-1, or the modification of DNA through the induction of apoptosis that renders the DNA immunogenic. The influence of sex hormones on the occurrence and manifestations of SLE in humans has not been documented in domestic species.

5.4.6.5

### IMMUNOLOGIC FACTORS

As discussed previously, SLE is characterized by a number of immunologic abnormalities and is clinically noted to have manifestations attributable to specific immune components. It is therefore reasonable to suggest that the pathogenesis of SLE involves aberrations of humoral and/or cell-mediated immunity. Previously, as a result of the documentation of autoantibodies in patients with SLE, it was hypothesized that the pathogenesis centered on an intrinsic B lymphocyte defect. Additionally, polyclonal B lymphocyte activation is a common immunologic abnormality seen in patients with SLE and in animals that are models for the disease. Recent studies, however, indicate that the autoantibodies associated with the development of clinical SLE are not the result of polyclonal B-lymphocyte activation, but rather the result of antigen-specific helper T-lymphocyte-dependent B-lymphocyte responses. This observation is consistent with our overall understanding of autoimmunity, and the current hypothesis is that these diseases are more likely to be the result of an immunologic dysregulation centered on helper T lymphocytes. The currently proposed model for the pathogenesis of SLE is presented in [Fig. 5-30](#). This model is an oversimplification of a complex disease with genetic and nongenetic factors that contribute to the development of a complex multisystemic disease with numerous clinical presentations, a progressive disease course, and an absence of specific cause.

236

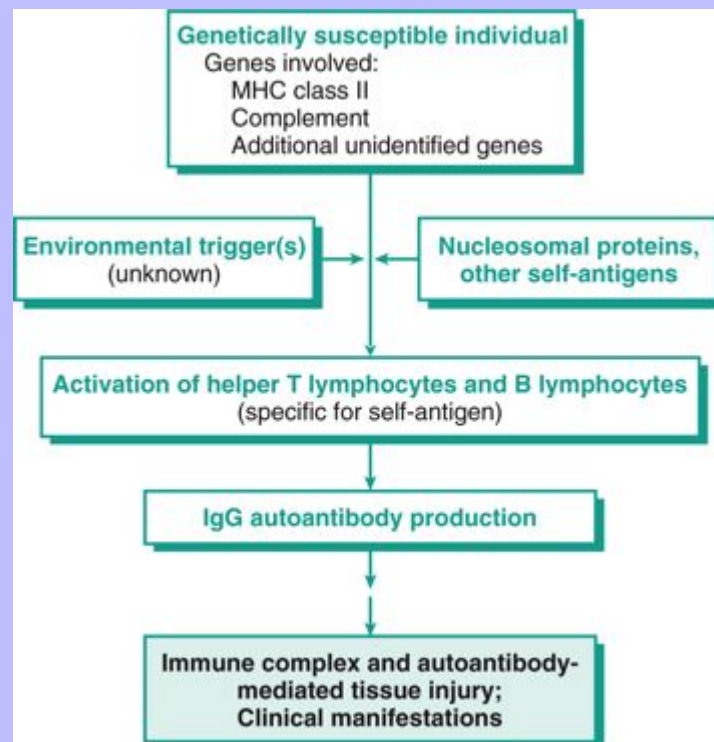

237

## Pathologic Basis of Veterinary Disease, 4th Edition

Although the underlying cause of autoantibody production in SLE remains unknown, the elaboration of antibody-peptide complexes are central to the mechanism of tissue damage. The majority of lesions in SLE are the result of immune complex disease (type III hypersensitivity). Antibodies directed against cell surface antigens also lead to the destruction of leukocytes, red blood cells, and platelets through direct cell lysis and enhanced removal by opsonization and phagocytosis. ANAs bind to cell-free nuclei to produce characteristic hematoxylin bodies or lupus erythematosus (LE) bodies. These bodies are frequently found in the skin, kidney, lung, lymph node, spleen, and heart of patients with SLE. These ANAs can also lead to the formation of LE cells, which are typically present in the bone marrow and are a phagocytic cell (macrophage or neutrophil) that has engulfed an opsonized nucleus. This phenomenon is also used as an in vitro diagnostic test to demonstrate the presence of ANA (LE test or LE prep).

**Fig. 5-30 Systemic lupus erythematosus.** Proposed model for the pathogenesis of systemic lupus erythematosus. *IgG*, Immunoglobulin G; *MHC*, major histocompatibility complex. (Modified from Kotzin BL: *Cell* 65:303-306, 1996.)

In summary, SLE represents the prototypical multiorgan autoimmune disease with a highly variable clinical presentation, a complex cause, and pathogenesis involving multiple genetic and environmental factors and a multitude of immunologic abnormalities. The current pathogenesis suggests that these factors contribute to the activation of T and B lymphocytes, resulting in the production of autoantibodies directed against a number of self-constituents, namely molecules within the nucleus, in the cytoplasm, or on the cell surface.

### 5.4.7 RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an autoimmune disease characterized by the presence of rheumatoid factors (anti-IgG antibodies) and is recognized in most species. The disease is discussed in [Chapter 16](#).

### 5.4.8 SJÖGREN-LIKE SYNDROME

Sjögren-like syndrome is a systemic autoimmune disease characterized by keratoconjunctivitis sicca, xerostomia, and lymphoplasmacytic adenitis. In humans, Sjögren syndrome can manifest itself alone or in association with other autoimmune or immune-mediated diseases, such as rheumatoid arthritis, pemphigus, SLE, polymyositis, and immune-mediated thyroiditis. A Sjögren-like syndrome has been described in the dog and cat.

#### 5.4.8.1 ETIOLOGY AND PATHOGENESIS

The keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth) result from the lymphocytic infiltration and fibrosis of lacrimal and salivary glands (lymphoplasmacytic sialoadenitis). In humans the infiltrate is primarily composed of activated CD4<sup>+</sup> lymphocytes and fewer B lymphocytes and plasma cells. Affected dogs are frequently hypergammaglobulinemic and less frequently have identifiable ANAs and rheumatoid factors. Many human patients have ANAs, rheumatoid factors, and nonorgan specific autoantibodies. Two autoantibodies specific to Sjögren syndrome in humans are directed against ribonucleoproteins: SS-A (Ro) and SS-B (La), which are considered serologic markers of the disease. Although autoantibodies can be identified, there is no direct evidence that they are the primary cause of tissue injury in any species evaluated to date. With the identification of autoantibodies and the presence of T lymphocytes within affected tissues, it is likely that the disease is the result of immunologic dysregulation centered on helper T lymphocytes. Sjögren syndrome in humans also is weakly correlated with certain MHC alleles, suggesting that as in SLE, the presence of certain MHC alleles may predispose the development of the disease.

237

238

As with many autoimmune diseases, viruses are suspected as potential causal agents. In most species in which viruses have been implicated, the evidence is largely circumstantial and Koch's postulates have rarely been satisfied. The mechanisms by which infectious agents can induce autoimmunity were discussed earlier.

#### 5.4.8.2 CLINICAL SIGNS AND LESIONS

Dogs with Sjögren-like syndrome have an adult onset of conjunctivitis and keratitis. Other findings include gingivitis and stomatitis. A case reported in the cat was characterized by dry eyes and enlarged salivary glands. The keratoconjunctivitis frequently leads to blepharospasm and conjunctival hyperemia. The xerostomia leads to dysphagia. Involvement of tissues other than salivary and lacrimal glands, as is reported in about one third of human cases, has not been documented in the dog and cat. Human patients have lymph node involvement that is characterized as a pleomorphic infiltrate with increased mitoses, and are at a fortyfold increased risk for developing lymphoid malignancies. Microscopically the salivary and lacrimal glands are infiltrated predominately by lymphocytes ([Fig. 5-31](#)). In the cat, immunohistochemical analysis of lesions in these glands indicated that the predominant cell type was positive for CD79 (B lymphocyte marker) with fewer, scattered CD3<sup>+</sup> cells (T-lymphocyte marker) and plasma cells. A mild interstitial fibrosis was also noted.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 5.4.9 INFLAMMATORY MYOPATHIES

Inflammatory myopathies in domestic species comprise an uncommon, heterogeneous group of disorders that are characterized by skeletal muscle damage and inflammation. An immune-mediated pathogen is suspected. Four distinct disorders—masticatory muscle myositis, generalized inflammatory myositis, dermatomyositis, and extraocular myositis—are included in this category. They may occur alone or in association with other immune-mediated or autoimmune diseases. Of these diseases, only dermatomyositis is covered here; the remaining diseases are covered in [Chapter 15](#).

**Fig. 5-31 Lymphoplasmacytic sialoadenitis, Sjögren syndrome, salivary gland, cat.** Note the accumulation of lymphocytes and macrophages around salivary acini. H&E stain. (Courtesy Dr. P.W. Snyder, School of Veterinary Medicine, Purdue University.)

### 5.4.9.1 DERMATOMYOSITIS

Dermatomyositis is an inflammatory disease of the skin, muscles, and vasculature affecting primarily young dogs. The cause and pathogenesis are unknown. The disease has a higher incidence in the collie and Shetland sheepdog breeds, and in these breeds, it is often referred to as canine familial dermatomyositis, an inheritable inflammatory disease of the skin and muscle. The disease has also been diagnosed in a number of other breeds. A sex predilection has not been reported. The clinical and pathologic findings suggest that an immune-mediated or an autoimmune mechanism is involved in the pathogenesis.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

5.4.9.1.1

### Lesions

The dermatologic manifestations of the disease are variable but generally begin at an early age (between 2 and 6 months) and are characterized by alopecia and erythematous dermatitis that involve the face, ears, and bony prominences of the distal extremities. Erosions and ulcers are common early in the disease and scarring and pigmentary changes are seen in chronic cases. Histopathologically, degeneration and necrosis of basal cells of the epidermis and follicular epithelium are characteristic. Frequently, vacuolation of the basal epithelium leads to subepidermal cleft formation. Infiltration of the superficial dermis is often composed of lymphocytes, plasma cells, and macrophages with fewer mast cells and neutrophils.

238

Follicular atrophy and secondary ulceration and fibrosis can also be noted. The skeletal muscle

239

manifestations of the disease are a myositis composed of a variable infiltrate of primarily mononuclear inflammatory cells and occasional neutrophils. There are varying degrees of myofiber degeneration characterized by myofiber fragmentation, vacuolation, and hyalinization. In chronic cases, there may be fibrosis and evidence of myofiber regeneration. The temporal and masseter muscles are commonly involved, although in severe cases there may be generalized muscle involvement. Involvement of the esophageal muscles can lead to the development of megaesophagus.

5.4.10

### VASCULITIS

Vasculitis is inflammation of the walls of blood vessels. It is most often seen as a component of an underlying systemic disease process (e.g., infectious or neoplastic) or as an adverse reaction to drug or vaccine administration. In these instances, the pathogenesis involves a type III hypersensitivity reaction with the formation of immune complexes that are either formed in the vessel wall or formed in the circulation and lodge in the vessel wall. The inflammation of the blood vessel is not the result of an immunologic response to components of the blood vessel but rather an “innocent bystander” phenomenon with the formation or deposition of complexes in the wall and then activation of the complement system. The pathogenesis of a type III reaction was covered earlier in the chapter. An idiopathic febrile disease characterized by a systemic necrotizing vasculitis that occurs primarily in young (4 to 10 months of age) beagle dogs is suspected to be immune-mediated, based on clinical signs, immunologic abnormalities, and pathologic findings. The syndrome has been designated as juvenile polyarteritis or beagle pain syndrome, and there appears to be a familial predisposition in some colonies. A similar syndrome has been reported in other breeds. Males and females are equally affected.

5.4.10.1

### CLINICAL SIGNS AND IMMUNOLOGIC ABNORMALITIES

The classic presentation is a febrile (104° F to 107° F) young dog with anorexia, hunched stance, cervical pain, and an unwillingness to move the head and neck. The disease has a cyclic course, with two to seven periods of signs that resolve. They have a moderate to notable leukocytosis, with neutrophilia, nonregenerative anemia, and hypoalbuminemia. Cerebral spinal fluid analysis indicates a neutrophilic pleocytosis with mild to moderate increases in microprotein. On serum protein electrophoresis, they have a high  $\alpha_2$ -globulin fraction. ANA tests, LE preparations, and rheumatoid factor tests are generally negative.

Immunologic abnormalities include an increase in serum IgA concentration, an increase in the percentage of peripheral B lymphocytes, and a decrease in the percentage of total peripheral T lymphocytes, a marked suppression of the blastogenic response to mitogenic stimulation, an inability to generate immunoglobulin-secreting plasma cells following polyclonal activation, and evidence of monocyte-macrophage activation. There are increased concentrations of IL-6 in the serum of acutely affected

## Pathologic Basis of Veterinary Disease, 4th Edition

---

dogs, and these return to base-line concentrations during periods of remission or following corticosteroid therapy.

5.4.10.2

### LESIONS

Severe necrotizing vasculitis and perivasculitis with thrombosis of small- to medium-sized blood vessels in the leptomeninges of the cervical spinal cord, cranial mediastinum, and heart are commonly seen (Fig. 5-32). In severe cases, a more widespread distribution of vascular lesions occur and commonly involves the thyroid gland, small intestine, testes, diaphragm, esophagus, and urinary bladder. Most patients experience multiple episodes, but some may have only one to two episodes before becoming normal, and clinical signs appear to resolve in all but the most severely affected patients by 12 to 18 months of age. Some dogs that experience repeated acute episodes develop splenic, hepatic, and renal amyloidosis. The pathogenesis of amyloidosis is attributed to serum amyloid A production and the development of reactive systemic amyloidosis secondary to the vascular inflammation.

5.4.11

### IMMUNODEFICIENCY SYNDROMES

Immunodeficiency diseases occur when there is a failure of the immune system to protect the host from infectious organisms or the development of cancer. An immunodeficiency syndrome that is the result of a congenital or genetic defect in a component of the immune system is called a primary immunodeficiency. Although the defect may be present at birth, the disease may not be manifested until later in life. An immuno-deficiency syndrome that is an acquired loss of immune function as a complication of infections, malnutrition, or aging or a side effect of immunosuppression, irradiation, or chemotherapy for cancer or autoimmune disease is called a secondary immunodeficiency. It is important to differentiate between a primary and secondary state of immunodeficiency with respect to treatment and prognosis. In some instances, it is useful to subclassify immunodeficiency diseases into those that affect adaptive (specific) or noninnate (nonspecific) immune responses. The study of immunodeficiency diseases has provided valuable insights and has enhanced our understanding of the complexities of the immune system. The ability to specifically identify the defective component provides great potential for the development of screening tests and of effective therapies. Naturally occurring and experimentally induced defects have made significant contributions to the field of immunology. There are a greater number of well-characterized immunodeficiency diseases in humans that likely have a domestic animal counterpart that have not yet been recognized. With the advent of new reagents and methodologies for characterizing cells and components of the immune system of domestic species, there should be a better chance in identifying immunodeficiency syndromes. Most primary immunodeficiency diseases are inherited, and the gene defect has been identified. There are additional forms of immunodeficiency that are the result of developmental defects that impair the function of an organ of the immune system. Finally, secondary immunodeficiency is a component of a large number of diseases of domestic species (ranging from malnutrition to viral infections that target lymphoid cells) and is beyond the scope of this chapter. This portion of the chapter will cover some of the better characterized primary immunodeficiency diseases of domestic animals.

239

240

**Fig. 5-32 Perivasculitis and vasculitis, polyarteritis, beagle dog.** Note the accumulation of lymphocytes and macrophages around the arteriole. H&E stain. (Courtesy Dr. P.W. Snyder, School of Veterinary Medicine, Purdue University.)

### 5.4.11.1 PRIMARY IMMUNODEFICIENCIES

Most primary immunodeficiency diseases are the result of a genetic defect (inherited or congenital) and affect specific (i.e., humoral and cell-mediated arms of the adaptive immune response) or nonspecific immunity (i.e., components of innate immune responses, such as complement, phagocytosis, NK cells, etc.). Specific defects in adaptive immune responses can be divided into those affecting T lymphocytes or B lymphocytes or both (Fig. 5-33). As already discussed, interactions between B and T lymphocytes are necessary for the development of many immune responses. In some instances, the clinical distinction between a primary B-lymphocyte defect and a T-lymphocyte defect may not be obvious with respect to humoral immunity. For example, T-lymphocyte defects almost always result in impaired antibody synthesis and as such are indistinguishable from B-lymphocyte defects or combined B-lymphocyte and T-lymphocyte defects. In general, most primary deficiencies manifest themselves early in life and affected patients clinically have a failure to thrive and a susceptibility to recurrent infections. In many instances, the type of infection suggests to some extent the likely component of the immune system that is defective (Table 5-11). It is beyond the scope of this chapter to present all of the forms of human and rodent immunodeficiency, and thus only a few are referenced for clarity to facilitate understanding diseases that have been characterized in domestic species.

### 5.4.11.2 PRIMARY IMMUNODEFICIENCIES OF SPECIFIC IMMUNITY

#### 5.4.11.2.1 Severe Combined Immunodeficiency Disease

Severe combined immunodeficiency disease (SCID) is a family of genetic defects that have in common deficiencies in both humoral and cell-mediated immunity. In its extreme form, SCID results from a defect in the common lymphoid stem cell that results in defective cell-mediated and humoral immune responses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

More commonly, SCID defects affect either T lymphocytes or B and T lymphocytes and are best characterized in humans, mice, dogs, and horses. T-lymphocyte defects often clinically have a combined immunodeficiency because there is a secondary impairment of humoral immunity that is the result of an inability of the T lymphocyte to provide the necessary signals for B-lymphocyte activation. These defects result in an inability to generate a specific immune response and can have an autosomal recessive, X-linked, or sporadic inheritance pattern. The types of underlying defects are diverse and may involve enzyme systems or proteins necessary for lymphocyte development and differentiation, or signal transduction pathways involved in lymphocyte activation. Often the most common infectious manifestation of SCID is a viral or fungal infection. Immunity to viral and fungal infections is largely dependent on cell-mediated immunity. Immunity to most bacterial infections (especially extracellular bacteria) are largely dependent on humoral immunity, and neonates have adequate humoral immunity from the passive transfer of maternal antibodies that protect them.

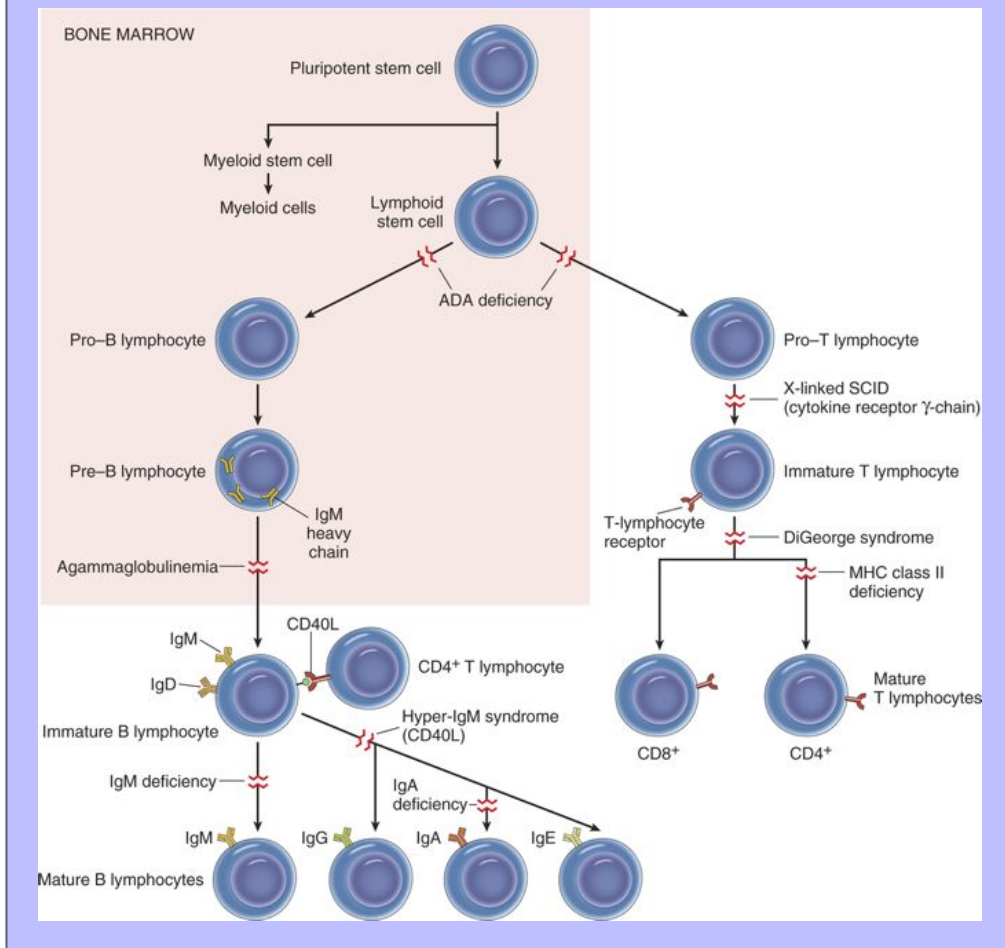

SCID in horses is an autosomal recessive disorder described in the Arabian or Arabian-cross breed. The defect results in a severe lymphopenia (less than  $1000/\text{mm}^3$ ) attributed to an inability to produce functional T and B lymphocytes. At birth, before they acquire maternal antibodies via colostrums, affected animals are deficient in serum IgM, and following catabolism of passively transferred antibodies, they have agammaglobinemia develop. Recurrent infections are typical and death is commonly the result of infection with equine adenovirus, *Pneumocystis carinii*, *Cryptosporidium parvum*, or a variety of common equine bacterial pathogens. Grossly the thymus is small and maybe undetectable. Microscopically, there is profound lymphoid hypoplasia of primary and secondary lymphoid tissue. Thymuses contain small lobules with no corticomedullary differentiation, few lymphocytes, Hassall's corpuscles, and occasional cysts. Spleens are characterized as having no lymphoid follicles, periarteriolar lymphoid sheaths, or plasma cells. Additionally, it has been noted that the lymphoid follicle sites in the spleen lack connective tissue stroma, and this characteristic can be used to differentiate hypoplasia from atrophy. Lymph nodes lack lymphoid follicles, plasma cells, and corticomedullary differentiation. The molecular basis for the defect has been identified as a spontaneous mutation in the gene encoding, the catalytic subunit of a DNA-dependent protein kinase (DNA-PKcs) that is located on chromosome 9. Affected foals have a complete absence of functional DNA-PKcs. DNA-PK is required for the recombination of immunoglobulin heavy chain and TCR genes during development, which when defective results in an inability to form functional V regions. Interestingly, as a result of the DNA-PKcs mutation, affected horses also are defective in their DNA repair mechanisms. The importance of DNA repair mechanisms in preventing the development of cancer (see [Chapter 6](#)) would suggest that affected foals and heterozygous carriers would be at an increased risk for cancer. Although affected foals rarely live beyond 5 months of age, heterozygous carriers do, and they have been observed to be at a greater risk for developing sarcoids, a locally aggressive fibroblastic cutaneous neoplasm.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 5-11 Examples of Infections in Immunodeficiencies

Pathogen Type	T-Lymphocyte Defect	B-Lymphocyte Defect	Granulocyte Defect	Complement Defect
Bacteria	Bacterial sepsis	Streptococci, staphylococci	Staphylococci, <i>Pseudomonas</i>	Pyogenic bacterial infections
Viruses	Cytomegalovirus, chronic infections with respiratory and intestinal viruses	Enteroviral encephalitis		
Fungi and parasites	<i>Candida</i> , <i>Pneumocystis carinii</i>	Intestinal giardiasis, aspergillosis	<i>Candida</i> , <i>Nocardia</i> , <i>Aspergillus</i>	
Special features	Aggressive disease with opportunistic pathogens, failure to clear infections, adverse reactions to attenuated vaccines	Chronic recurrent gastrointestinal infections, sepsis, meningitis	Neutrophilia	

SCID in dogs was first described in Basset hounds as an X-linked defect (XSCID) characterized by lymphopenia, with increased numbers of B lymphocytes and few to no T lymphocytes. The lymphopenia is not as profound as it is in foals with SCID. At approximately 6 to 8 weeks of age, as maternally derived antibody concentrations decline, they develop recurrent infections of the skin, respiratory, or gastrointestinal system. Phenotypically, there is a decrease in the number of circulating CD8<sup>+</sup> lymphocytes resulting in a CD4<sup>+</sup>:CD8<sup>+</sup> ratio of approximately 15:1 (compared with 2:1 in normal dogs) and normal percentages of B lymphocytes. Dogs with XSCID are hypogammaglobulinemic with normal serum IgM concentrations and decreased concentrations of IgG and IgA. Affected dogs rarely live past 4 months of age, and death is frequently attributed to septicemia or systemic viral infections. At necropsy, lymph nodes, tonsils, Peyer's patches, and the thymus are extremely small and may be undetectable. Microscopically, there is severe lymphoid hypoplasia with similar characteristic features as described previously for lymphoid tissues of the foal with SCID. Thymuses of affected puppies are small (approximately 10% the weight of age-matched controls) and are characterized by a lack of corticomedullary demarcation and small lobules with few to no lymphocytes (Fig. 5-34). Thymuses have markedly increased percentages of CD8/CD4 lymphocytes (46% versus 16% in age-matched controls) compatible with a block in T lymphocyte differentiation. Canine XSCID is due to a mutation in the common gamma ( $\gamma_c$ ) subunit of the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. These receptors, for five immunologically different cytokines, belong to the type I cytokine receptor family. A four base pair deletion results in a stop codon that prevents full translation of the  $\gamma_c$  mRNA. T lymphocytes are nonfunctional due to an inability to express a functional IL-2 receptor. B lymphocytes are only activated by T-lymphocyte-independent antigens, and although they are capable of synthesizing IgM, they are incapable of class-switching to IgG. A similar molecular form of XSCID has also been described in the Cardigan Welsh Corgi breed. An insertional mutation, due to the insertion of a cytosine in exon 4, also results in a stop codon preventing complete translation of  $\gamma_c$  mRNA. In human SCID, mutations of the  $\gamma_c$  are the most common molecular mechanism with numerous distinct point, insertion, and deletion mutations identified. An autosomal recessive form of SCID has been described in Jack Russell terriers that is the result of a mutation in DNA-PKcs similar to that described previously in the Arabian horse and the CB-17 mouse.

SCID in mice occurs in the CB-17 strain and is an autosomal recessive trait characterized by an absence of mature B and T lymphocytes. The molecular basis for the SCID phenotype is attributed to a defect

## Pathologic Basis of Veterinary Disease, 4th Edition

---

resulting in decreased DNA-PK enzyme activity. Although mice are highly susceptible to opportunistic infections, they can be maintained in environments that minimize their exposure to pathogenic agents and kept alive for more than a year of age. An interesting, although poorly understood, immunologic finding in older (greater than 6 months of age) mice with SCID is the ability to produce small quantities of immunoglobulin and low numbers of mature T lymphocytes. This phenotype is referred to as “leaky SCID.” This leaky phenotype has not been described in other forms of SCID. As in other species with defective DNA repair mechanisms, there is an increased sensitivity to ionizing radiation damage.

5.4.11.2.2

### Common Variable Immunodeficiency

Common variable immunodeficiency is a primary immunodeficiency disease characterized by an adult onset of hypogammaglobulinemia attributed to an intrinsic B-lymphocyte defect, which results in an inability to produce much of the antibody. The disease has been described in a litter of miniature

242

Dachshund dogs. The dogs were characterized as having an absence of B lymphocytes in lymphoid tissues and little to no serum immunoglobulins. At necropsy, the affected animals had lesions characterized as atrophy of lymphoid tissue and pneumonia. Lymph nodes were further characterized as lacking lymphoid follicles. The pneumonia was caused by *Pneumocystis carinii*, a common opportunistic pathogen in immunocompromised animals and humans. In humans there have been a number of identified defects intrinsic to B lymphocytes that prevents their terminal differentiation and affects their ability to produce immunoglobulin, thus the designation as variable immunodeficiency. A similar disease has also been described in a 12-year-old Quarter Horse, which was characterized by hypogammaglobulinemia and an absence of B lymphocytes in circulation, bone marrow, and spleen.

243

Fig. 5-34 **X-linked severe combined immunodeficiency disease (XSCID) thymuses, normal puppy and littermate.** **A**, The gland from the normal puppy (*left*) weighed 7.4 g, and the gland from the XSCID puppy (*right*) weighed 0.2 g. **B**, Thymus from a normal neonatal dog (*left*) and from a neonatal dog with XSCID (*right*). The normal thymic lobule has a pale medullary region and a dark cortical region that is densely packed with small lymphocytes. The XSCID thymus has small lobules with no corticomedullary distinction and a paucity of small lymphocytes. H&E stain. (**A and B**, Courtesy Dr. P.W. Snyder, School of Veterinary Medicine, Purdue University.)

### 5.4.11.2.3

#### Agammaglobulinemia

Agammaglobulinemia is a primary immunodeficiency characterized by an inability to produce immunoglobulins and an absence of mature B lymphocytes and plasma cells. The disease has been described in Thoroughbred, Quarter Horse, and Standardbred breeds of horses. To date, all cases have been males, suggesting that, as in the human disease, it is an X-linked trait. Microscopically, there was an absence of plasma cells, primary follicles, and germinal centers in lymph nodes. Affected horses commonly have extracellular bacterial infections of the joints and respiratory system. In humans there is a mutation of the BTK gene located on the X chromosome that encodes a tyrosine kinase that results in an

## Pathologic Basis of Veterinary Disease, 4th Edition

arrest of B-lymphocyte development at the pre-B stage. The disease in humans is referred to as X-linked agammaglobulinemia (XLA).

5.4.11.2.4

### Selective Immunoglobulin Deficiencies

Selective deficiencies are represented by a number of diseases characterized by a deficiency of an individual class of immunoglobulin. Forms of these diseases have been identified and described in horses and dogs. The most common forms are selective IgM deficiency and selective IgA deficiency, characterized by a serum level of IgM or IgA, respectively, that is at least 2 standard deviations below normal. Serum concentrations of other classes of immunoglobulin are normal, and B lymphocyte numbers are normal. These deficiencies may not result in clinical signs until there is degradation of passively transferred maternal antibody. In horses, there are distinct forms of selective IgM deficiency with most affected animals succumbing to septicemia or pneumonia by 10 months of age. A few affected foals live beyond 10 months and commonly die of recurrent respiratory infections before reaching adulthood. Some horses reach adulthood before they show clinical signs of selective IgM deficiency. Selective IgA deficiency has been described in a number of breeds of dogs, including the German shepherd, Shar-Pei, Irish setter, and beagle. Because of the importance of IgA in mucosal immunity, many affected animals have respiratory, gastrointestinal, and skin infections. Some affected dogs, like human patients with IgA deficiency, have a predisposition to developing atopic disease. In most instances there are normal numbers of IgA-producing plasma cells, suggesting an inability to synthesize or secrete IgA. Although the molecular basis for selective immunoglobulin deficiencies is unknown, they are thought to relate to the differentiation of naïve B lymphocytes into immunoglobulin-secreting plasma cells.

5.4.11.2.5

### Thymic Hypoplasia

Thymic hypoplasia represents a number of immuno-deficiency diseases characterized by a failure to develop a functional thymus, resulting in a T-lymphocyte deficiency. Mice homozygous for the genetic trait nu (nu/nu) are hairless, and this athymic strain is commonly referred to as the nude mouse. Affected mice have a developmental arrest of the thymus, which occurs around day 12 of gestation and results in an absence of a functional thymus. Nude mice have defective cell-mediated immune responses and are unable to develop antibody responses. The immunologic abnormalities are attributed to a deficiency of T-lymphocyte responses. Heterozygous (nu/+) animals are normal. The few circulating T lymphocytes in affected mice have TCRs of the  $\gamma/\delta$ -type rather than the  $\alpha/\beta$ -type. Under conventional housing conditions, mortality is high during the first 2 weeks of life; however, when maintained in germfree environments, they can survive longer. This strain of mice is an important animal model, as they can tolerate allografts and xenografts. Similar, although less well-characterized, hairless and athymic conditions have been described in other species. A condition in humans characterized by thymic hypoplasia is referred to as DiGeorge syndrome. DiGeorge syndrome is a T lymphocyte deficiency resulting from an embryologic defect affecting the development of the third and fourth pharyngeal pouches. Affected humans have thymic (fourth pharyngeal pouch) and parathyroid (third pharyngeal pouch) defects. They have decreased circulating T lymphocytes, and T-lymphocyte areas of lymphoid tissues (paracortical areas of lymph nodes and periarteriolar sheaths of the spleen) are depleted of lymphocytes. There is an absence of cell-mediated immune responses. DiGeorge syndrome is not familial, but rather the result of the deletion of a specific gene that is a member of the T-box family of transcription factors. Specifically, how or why this transcription factor influences the development of the thymus and parathyroid is unknown.

### 5.4.11.3 PRIMARY IMMUNODEFICIENCIES OF NONSPECIFIC IMMUNITY

#### 5.4.11.3.1 Deficiencies of the Complement System

The complement system contains more than 30 soluble and cell-bound proteins that influence immune and inflammatory responses. The pathways of complement activation, regulation of the complement system, and biologic consequences of complement activation have been previously covered in [Chapter 3](#). In humans, inherited deficiencies have been described for nearly all components and two of the inhibitors. Although a deficiency of C2 is the most common, humans with deficiencies in components of the classical pathway have little to no increased risk for infections, suggesting that the alternative and lectin pathways of activation are sufficient for controlling infections. Deficiencies of the classical pathway components are associated with an increased incidence of SLE-like autoimmune disease, which has been attributed to impaired clearance of immune complexes by the monocyte-macrophage system. Although deficiencies of components of the alternative pathway (properdin and factors D and H) are rare, when they do occur they are associated with recurrent pyogenic infections. A deficiency of C3, which is required for all three pathways of complement, is the most serious deficiency and results in serious recurrent infections. An autosomal recessive trait resulting in a genetically determined deficiency of C3 has been described in the Brittany spaniel dog. Homozygous dogs have serum concentrations of C3 and also opsonic and chemotactic activities that are severely decreased compared with normal dogs. Affected dogs are predisposed to recurrent infections and type 1 membranoproliferative glomerulonephritis. Bacterial infections with *Clostridium* spp., *Escherichia coli*, and *Klebsiella* spp. resulting in pneumonia, septicemia, and pyometra, respectively, are the most common clinical manifestations.

The molecular basis for the deficiency has been identified as a deletion mutation that results in a premature stop codon, preventing adequate translation and resulting in decreased concentrations of mRNA. Heterozygous dogs have serum concentrations of C3 that are approximately 50% of normal, but these dogs are clinically normal. C3 deficiency has also been described in guinea pigs and rabbits.

An autosomal recessive trait resulting in a deficiency of factor H, a component of the alternative pathway of complement, has been described in the Norwegian Yorkshire breed of pig. Factor H is a regulator of complement activation that blocks the formation of C3 convertase and is a cofactor for cleavage of C3b by factor I. Deficiencies of factor H result in unregulated elaboration of C3b upon activation of the alternative pathway. The most common clinical manifestation is renal disease. Affected pigs develop a type II membranoproliferative glomerulonephritis characterized by glomerular changes consisting of thickened capillary walls, proliferation of mesangial cells, dense intramembranous deposits, and glomerular deposits of C3 components. The disease is commonly referred to as porcine dense deposit disease.

The molecular basis for the decreased serum concentrations of factor H has been reported to be the result of nucleotide sequence alterations in the factor H gene that cause a block in protein secretion. Hepatocytes of affected animals have increased intracellular concentrations of factor H. Hereditary factor H deficiency in humans can be characterized by a variety of clinical manifestations ranging from recurrent bacterial infections to glomerular disease to hemolytic uremic syndrome. Deficiencies of the terminal components (C5, C6, C7, C8, and C9), which are required for the formation of the membrane attack complex and the lysis of cell membranes, do occur and generally result in increased bacterial infections.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Deficiencies of C1 inhibitor and other complement regulatory proteins, although described in humans, have yet to be described in domestic animals. C1 inhibitor deficiency is an autosomal dominant trait that causes hereditary angioedema. C1 inhibitor is a protease inhibitor that targets C1r and C1s enzymes of the classical pathway of complement, Hageman factor (factor XII) of the coagulation pathway, and the kallikrein system. As indicated in [Chapter 4](#), these three pathways are closely linked and result in the elaboration of vasoactive amines, notably bradykinin. Affected human patients develop episodes of edema involving the skin and mucosal membranes, such as those of the larynx and gastrointestinal system. Deficiencies of membrane-bound regulator proteins, such as decay-accelerating factor and homologous restriction factor, result in paroxysmal nocturnal hemoglobinuria. In the absence of these regulatory factors, red blood cells can be more easily lysed by concentrations of complement that are much lower than normally required. The increased lysis of red blood cells causes chronic hemolytic anemia and hemoglobinuria.

5.4.11.3.2

### Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is an inherited disease caused by defective lysosomes, melanosomes, platelet-dense granules, and cytolytic granules. The disease has been described in cats, cattle, killer whales, beige mice, rats, Aleutian mink, and humans. Common clinical manifestations of the disease may include hypopigmentation, a bleeding tendency, ocular abnormalities, and recurrent infections. Some species are more susceptible to recurrent infections than others. The hallmark of the disease is the presence of enlarged granules within melanocytes, neutrophils, eosinophils, and monocytes. The enlarged granules are melanosomes (melanocytes), lysosomes (many cell types), or cytoplasmic granules (e.g., fused primary and secondary granules of neutrophils). Neutrophils containing giant granules have impaired functions, such as defective chemotaxis and intracellular killing. NK cells are also defective and may also contribute to the increased susceptibility to infections reported in some species. Mink with Chédiak-Higashi syndrome have an increased susceptibility to Aleutian mink disease virus. The hypopigmentation is the result of an inability of melanocytes, containing abnormally large melanosomes, to migrate and release their contents, resulting in a deficiency of pigment most commonly evident in the skin, hair, and eye. The bleeding tendency is a coagulopathy resulting from defective platelets. Platelet counts are generally normal. In most species studied, most recently cattle, there is insufficient platelet aggregation because of a decreased response to collagen. Research suggests that the GPIIb/IIIa ( $\alpha_2\beta_1$ -integrin) glycoprotein or rhodocytin pathway of platelet activation may be defective. Ocular abnormalities identified in cattle, cats, mink, mice, and humans are similar and are characterized by abnormal ocular pigmentation and an associated photophobia. Cats with Chédiak-Higashi syndrome frequently develop cataracts. The molecular basis for Chédiak-Higashi syndrome has been identified in some human forms and in beige mice and cattle to be a result of a mutation of the Lyst gene. The Lyst gene encodes a membrane-associated protein, which is thought to regulate intracellular protein trafficking. Exactly how the protein regulates intracellular trafficking remains unknown.

5.4.11.3.3

### Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency (LAD) is a primary immunodeficiency disease characterized by the inability of leukocytes to migrate from circulation into sites of inflammation, resulting in recurrent bacterial infections (see [Chapter 3](#)). The disease is best characterized in humans and in bovine (BLAD) and canine (CLAD) species, in which the defect is inherited as an autosomal recessive trait. The Irish setter breed of dogs and Holstein breed of cattle are commonly affected domestic species. The hallmark of the disease is a profound leukocytosis characterized by a marked neutrophilia, and the disease was

## Pathologic Basis of Veterinary Disease, 4th Edition

initially referred to in these species as canine granulocytopathy syndrome and bovine granulocytopathy syndrome, respectively. In Irish setters, CLAD-affected puppies often initially have omphalophlebitis just after birth and by 4 months of age commonly have episodes of gingivitis, osteomyelitis, or lymphadenopathy. An inability to form pus and delayed wound healing may also be observed. Dogs rarely survive beyond 6 months of age as a result of the recurrent infections. In affected calves, BLAD causes a similar spectrum of recurrent infections and leads to death by 7 months of age. The molecular basis for the disease is a defective expression of the $\beta_2$ -integrin subunit of a large group of heterodimeric ( $\alpha$ - and $\beta$ -subunits) leukocyte adhesion molecules. The $\beta_2$ -integrins are a family of adhesion molecules that all share the same $\beta$ -subunit (CD18), but have unique $\alpha$ -subunits (CD11a, b, c). Members of the $\beta_2$ -integrin family include: leukocyte function-associated antigen, LFA-1 (CD11a/CD18); Mac-1 or complement receptor 3 (CD11b/CD18); and p150,95 or CR4 (CD11c/CD18). As discussed in <a href="#">Chapter 3</a> , these surface molecules are in part required for neutrophil adhesion to the endothelium and extravasation into the tissue, migration to sites of inflammation or infection (chemotaxis), and phagocytosis of C3b-opsonized bacteria. The binding of neutrophils to cytokine-activated endothelial cells at sites of inflammation is also mediated in part by selectins, which are not affected in LAD. Therefore in LAD, neutrophils marginate, but fail to migrate from the endothelium. Human, bovine, and canine LAD are caused by missense mutations in the $\beta_2$ -integrin subunit gene, resulting in a functionally defective $\beta_2$ -integrin protein.	245 246
---	------------

### 5.4.12 AMYLOIDOSIS

Although there is no evidence to suggest that amyloidosis is always the result of a primary immunologic abnormality, the pathogenesis of amyloidosis may involve components of the immune system and as such is discussed here. Amyloidosis represents a broad spectrum of clinical and pathologic conditions that all have in common the deposition of amyloid material. Amyloid is a pathologic proteinaceous substance of different chemical entities with an identical conformational property of forming $\beta$ -pleated sheets of nonbranching fibrils as identified by x-ray crystallography and infrared spectroscopy ( <a href="#">Fig. 5-35</a> ). By light microscopy, and standard hematoxylin and eosin staining, amyloid appears as an amorphous, eosinophilic, hyaline, extracellular substance that with progressive accumulation results in pressure atrophy of adjacent cells and tissue ( <a href="#">Fig. 5-36</a> ).	246
Although amyloid can be derived from different chemical entities, all deposits have the same appearance and tinctorial characteristics. In humans, there are three major and several minor biochemical forms. Amyloidosis is a feature of several different pathologic mechanisms and as such should not be considered a single disease, but rather a group of diseases having in common the deposition of similar-appearing proteins. It is often necessary to differentiate amyloid from other similar-appearing extracellular deposits, such as collagen and fibrin. Differentiating these proteins is readily accomplished using histochemical techniques. The most common technique for identifying amyloid is the Congo red stain, which does not have chemical specificity for amyloid but is dependent on the conformational property of being arranged in $\beta$ -pleated sheets. Congo red stains amyloid an orange to red color, and when viewed by polarized light reveals a characteristic green birefringent material (see <a href="#">Chapter 11</a> ). A loss of Congo red staining by pretreating sections with potassium permanganate may suggest that the amyloidogenic protein is of amyloid-associated origin (see next section).	247

Fig. 5-35 Schematic depiction of amyloid fibrils,  $\beta$ -pleated sheets, and binding sites for Congo red dye. (Modified from Glenner GG: *N Engl J Med* 52:148, 1980.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 5.4.12.1 CHEMICAL NATURE OF AMYLOID

Amyloid contains approximately 95% fibrillar proteins and 5% P component and other glycoproteins. Of the 15 biochemically distinct forms of amyloid recognized in humans, 3 are most common: (1) amyloid light chain (AL), derived from immunoglobulin light chains of plasma cells; (2) amyloid associated (AA), derived from the acute phase protein serum amyloid A (SAA); and (3) A $\beta$  amyloid, derived from amyloid precursor protein (APP). These forms of amyloid are also recognized in domestic species.

The AL form of amyloid can contain complete immunoglobulin light chains, the NH<sub>2</sub>-terminus portion of immunoglobulin light chains, or both. Of the two immunoglobulin light chains,  $\lambda$  and  $\kappa$ , most AL forms consist of  $\lambda$ -light chains or their fragments. Immunoglobulin-secreting cells, B lymphocytes, and plasma cells are associated with deposition of AL amyloid.

The AA form of amyloid consists of a proteolytic fragment of a larger acute phase protein called SAA, which is found in the plasma and is synthesized in the liver and released during systemic inflammatory reactions.

The A $\beta$  form of amyloid contains a proteolytic fragment of the APP and is associated with the cerebral amyloid angiopathy of Alzheimer's disease in humans and with some forms of neurodegeneration in the canine brain. This form of amyloid will be discussed more extensively in [Chapter 14](#).

Of the large number of other biochemically distinct proteins that have been associated with the formation of amyloid in a number of human clinical diseases, only a few are relevant to domestic species. One of these is islet amyloidosis, affecting the feline pancreas. Islet amyloid is derived from islet amyloid polypeptide (IAPP), which is a hormone synthesized by the  $\beta$  cells of the pancreatic islets. All forms of amyloid contain other minor components, including serum amyloid P protein, proteoglycans, and glycosaminoglycans. Serum amyloid P may function to stabilize the fibrils and decrease their susceptibility to proteolysis.

### 5.4.12.2 CLASSIFICATION OF AMYLOIDOSIS

In addition to the classification based on the primary biochemical constituent as discussed previously, it is also useful from a pathologist's perspective to categorize these conditions according to their clinical disease and pathogenesis ([Table 5-12](#)). Amyloid can be systemic (generalized), with deposits in many organ systems, or it can be localized, with deposits limited to a single organ. The systemic or generalized category can be further subclassified into primary amyloidosis (AL), when associated with immunocyte dyscrasia, or secondary amyloidosis (SAA), when associated with a chronic inflammatory or destructive tissue process. Hereditary or familial amyloidosis comprises a separate heterogeneous category with several distinctive patterns of organ involvement that are primarily recognized in humans.

#### 5.4.12.2.1 Primary Amyloidosis

Primary amyloidosis is the most common systemic form of amyloidosis and is of the AL type. Many cases of AL amyloidosis are attributable to the presence of some type of immunocyte dyscrasias. The most common immunocyte dyscrasias associated with AL amyloidosis in domestic species is a neoplasm of plasma cells. Plasma cell-derived neoplasms include the extramedullary plasmacytoma and the myeloma or more common multiple myeloma that are most often limited to the bone marrow. Although neoplastic plasma cells often synthesize abnormal amounts of complete immunoglobulin or components of

## Pathologic Basis of Veterinary Disease, 4th Edition

immunoglobulins (light or heavy chain only), only a small percentage of patients with these neoplasms develop amyloidosis. On serum protein electrophoresis, there may be a monoclonal gammopathy that is compatible with the presence of a single specific immunoglobulin. Additionally, in some cases the serum may contain only the light chain component (referred to as Bence Jones protein). Because an individual plasma cell can only synthesize either the  $\lambda$ - or  $\kappa$ -type of light chain and because plasma cell-derived neoplasms are of clonal origin, only one light chain type will be present. The  $\lambda$ -light chain is most often identified in AL-type amyloidosis. Because light chains are small proteins (approximately 50 kD), they are frequently detected in the urine of affected patients. The mere presence of Bence Jones proteins itself is not sufficient to produce AL amyloidosis, as many cases of plasma cell neoplasms with identifiable Bence Jones proteins occur in most domestic species without the development of amyloidosis. In contrast to amyloidosis in humans, in which the majority of patients with AL amyloid do not have any overt B lymphocyte or plasma cell neoplasm but do have monoclonal antibodies or light chains in their serum or urine, domestic species rarely have AL-type amyloid without evidence of an immunocyte dyscrasias. A more complete discussion of these neoplasms may be found in [Chapter 13](#).

247

248

Table 5-12 Classification of Amyloidosis

Clinicopathologic Category	Associated Diseases	Major Fibril Protein	Chemically Related Precursor Protein
<b>SYSTEMIC (GENERALIZED) AMYLOIDOSIS</b>			
Immunocyte dyscrasias with amyloidosis (primary amyloidosis)	Multiple myeloma and other monoclonal B-cell proliferations	AL	Immunoglobulin light chains, chiefly $\lambda$ -type
Reactive systemic amyloidosis (secondary amyloidosis)	Chronic inflammatory conditions	AA	SAA
Familial amyloidosis	Some animals have systemic deposition of amyloid in addition to renal deposits	AA	
<b>LOCALIZED AMYLOIDOSIS</b>			
Amyloid of aging	Neurodegenerative disease, senile plaques, cerebral amyloid angiopathy	A $\beta$	APP
Endocrine tumors	Amyloid-producing odontogenic tumor, ameloblastomas	A Cal	Calcitonin, polypeptide hormones or prohormones
Nonendocrine tumors	Diabetes mellitus	IAPP	Islet amyloid polypeptide
Islets of Langerhans	—	Apolipoprotein A-1	Apolipoprotein A-1
Isolated amyloid of pulmonary vasculature	Various prion diseases of the CNS, spongiform encephalopathy	Misfolded prion protein (PrP <sup>Sc</sup> )	Normal prion protein PrP
Prion diseases	Renal disease	AA	Likely SAA
Familial amyloidosis of the dog	Renal disease	AA	Likely SAA
Familial amyloidosis of the cat	Age-related finding		Unknown (not AA)
Gastrointestinal amyloidosis			

A Cal, Amyloid of hormone origin; AA, amyloid associated; AL, amyloid light chain; APP, amyloid precursor protein; CNS, central nervous system; IAPP, islet amyloid polypeptide; SAA, serum amyloid A.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 5.4.12.2.2 Reactive Systemic Amyloidosis

This form of amyloidosis has a systemic distribution and is also referred to as secondary amyloidosis because it is often secondary to a chronic inflammation of the destructive tissue process. Reactive systemic amyloidosis in domestic animals is a form of AA amyloid, which is most often either secondary to chronic inflammatory or neoplastic (nonimmunocyte dyscrasias) conditions or idiopathic, where no underlying disease is found. A prolonged increased serum concentration of SAA protein is necessary but by itself insufficient for the development of AA amyloid. This form of amyloidosis is recognized in most species. A form of the disease is also recognized in captive cheetahs and closely related Siberian tigers. In the cheetahs, in which renal deposits were primarily in the medullary interstitium, inflammatory conditions, most often gastritis, were found in all affected cats.

### 5.4.12.2.3 Familial Amyloidosis

This is a systemic form of AA amyloidosis that is hereditary in some breeds of cats and dogs. Familial AA amyloid has been described in the Abyssinian and Siamese breeds of cat and the Shar-Pei breed of dog. The organ systems affected are varied, but deposits most commonly occur in the kidney (primarily a glomerular deposition in the Abyssinian cat and medullary interstitium deposition in the Shar-Pei dog) and liver (Siamese cat). The amyloid fibrils consist of AA proteins, suggesting that this form may be related to chronic inflammatory conditions. Preliminary analysis of the different isoforms of SAA in the cat suggests that certain SAA genes may contribute to the development of this form of amyloid. Most domestic species have at least three isoforms of SAA.

248

249

### 5.4.12.2.4 Localized Amyloidosis

Occasionally, amyloid deposits are limited to a single organ or tissue. In many instances, the localized deposits are grossly visible as masses. Localized amyloidosis is present in calcifying epithelial odontogenic tumors (amyloid-producing odontogenic tumor) of the cat and dog. Of the prominent features of these rare neoplasms, one is the presence of amyloid, which often calcifies. Some forms of naturally occurring transmissible spongiform encephalopathies, such as chronic wasting disease (CWD), are characterized by amyloid plaques in the brain in addition to the intraneuronal vacuolation. The lesions of CWD and other prion diseases are discussed in [Chapter 14](#).

### 5.4.12.2.5 Endocrine Amyloidosis

Deposition of amyloid in the pancreas of cats, nonhuman primates (macaques and baboons), and humans can lead to the development of type 2 diabetes mellitus. The amyloid is deposited in the pancreatic islets and is derived from islet amyloid polypeptide (IAPP), a normal protein secreted by the  $\beta$  cell of the pancreas. How a normal protein product becomes amyloidogenic in some instances remains unknown. It is not known if the deposition of amyloid and the development of clinical diabetes mellitus is the result of progressive loss of  $\beta$  cells from the amyloid or if the deposition of amyloid occurs as a result of prolonged stimulation of the  $\beta$  cells as a consequence of insulin resistance. The disease in cats is discussed in [Chapter 11](#). Amyloid deposition can also occur in the cortex of the adrenal gland; however, it is not associated with any functional deficiencies.

### 5.4.12.2.6 Amyloid of Aging

Amyloid deposition can occur as an age-related change in a number of organ systems. Similar to senile systemic amyloidosis in humans, old dogs can develop neurodegenerative changes that may include cerebrovascular amyloidosis or the formation of senile plaques. These deposits can consist of a number of extracellular proteins, but most commonly contain A $\beta$  type amyloid. Other organ systems rarely containing amyloid deposits in the aged dog are heart, gastrointestinal tract, and lungs. The deposition of amyloid in the pulmonary vasculature of aged dogs was reported to be derived from apolipoprotein AI (Apo AI). These forms of amyloidosis are discussed in the appropriate chapters covering these respective organ systems.

### 5.4.12.3 PATHOGENESIS OF AMYLOIDOSIS

Amyloid deposition is the result of abnormal folding of pathogenic proteins, deposited extracellularly as fibrils organized into  $\beta$ -pleated sheets. Although there are many diverse proteins associated with the formation of amyloid, they are all characterized by misfolded proteins leading to the formation of fibrils that are unstable and self-associated. Equally diverse are the number of conditions that can be associated with the formation of amyloid, and each of these conditions are characterized by excessive production of amyloidogenic proteins that are prone to misfolding. The two general categories of amyloidogenic proteins are: (1) those that are normal proteins that have an inherent tendency to misfold and form fibrils when produced in excess quantities, and (2) those that are abnormal protein products as a result of genetic mutations that are structurally unstable and form fibrils that self-associate. Misfolded proteins are normally degraded intracellularly within proteasomes or extracellularly by macrophages. In amyloidosis, these degradative processes are inadequate and may be responsible for the accumulation of misfolded proteins extracellularly. A simplified pathogenic scheme for the major forms of amyloidosis is presented in [Fig. 5-37](#). As discussed previously, the overproduction of a precursor protein, although necessary, by itself is not sufficient to result in the formation of amyloid. In secondary reactive systemic amyloidosis, a component of a systemic inflammatory reaction results in the activation of macrophages that elaborate endogenous pyrogens IL-1 and IL-6, which stimulate hepatocytes to synthesize and secrete SAA.

During an inflammatory reaction, the quantity of SAA in the serum may increase several 100 times normal concentrations; however, not all systemic inflammatory reactions result in the formation of AA amyloid. Why is it that only some inflammatory reactions lead to amyloidosis? Two theories, one based on a defective degradation system for SAA and one based on an abnormal SAA protein that is resistant to degradation, have been proposed. SAA is normally degraded to soluble protein products by enzymatic components of the monocyte-macrophage system. An enzymatic defect in this system may result in incomplete degradation and the production of insoluble AA molecules that form fibrils. Alternatively, a mutation of an SAA gene may result in the synthesis of an abnormal SAA protein that is resistant to degradation and prone to producing insoluble AA molecules that form fibrils. Finally, in the AL form of amyloidosis plasma cells synthesize excessive quantities of immunoglobulin light chains that are resistant to complete degradation and susceptible to forming insoluble fibrils. Although there have been numerous attempts to identify specific sequence motifs unique to AA and AL forms of amyloid, to date none has been identified. Another research interest has focused on the existence of the diversity of SAA isoforms and their relationship to the formation of AA amyloid.

249

The diagram is a flowchart with a light blue background. At the top, two main categories are listed: 'PRODUCTION OF ABNORMAL AMOUNTS OF PROTEIN' and 'PRODUCTION OF NORMAL AMOUNTS OF MUTANT PROTEIN (e.g., transthyretin)'. Below these, four vertical pathways are shown, each starting with a 'STIMULUS' and leading to a final product. The first pathway, under 'STIMULUS:', leads to 'SOLUBLE PRECURSOR: MISFOLDED PROTEIN' and then to 'INSOLUBLE FIBRILS'. The second pathway, under 'Unknown (Carcinogen?)', leads to 'Monoclonal B-lymphocyte proliferation', then 'Plasma cells', then 'Immunoglobulin Light Chains', and finally 'AL PROTEIN' (with 'Limited proteolysis' noted). The third pathway, under 'Chronic Inflammation', leads to 'Macrophage activation', then 'Interleukin 1 and 6', then 'Liver cells', then 'SAA Protein', and finally 'AA PROTEIN' (with 'Limited proteolysis' noted). The fourth pathway, under 'Mutation', leads to 'Abnormal Protein' and then to 'ABNORMAL PROTEIN'. Arrows indicate the flow from top to bottom in each column.

MORPHOLOGY OF AMYLOIDOSIS
---------------------------

Grossly affected organs are often enlarged, moderately firm, and abnormally discolored. In some instances, the application of an iodine solution (e.g., Lugol's iodine) to an affected tissue may stain the deposits brown, which develops into a blue-violet color when exposed to dilute sulfuric acid solution.

## 6 Chapter 6 Neoplasia and Tumor Biology

DONNA F. KUSEWITT

LAURA J. RUSH

Despite the relatively short life span of most animals, neoplasia is an important concern for veterinary practitioners, diagnosticians, and researchers. Tumor diagnosis and treatment for individual animals is becoming an increasingly prominent part of small animal practice. In food animals, infectious and environmental causes of cancer can have a major impact on herd or flock health. Furthermore, animal models provide important insights into the cause and treatment of human cancer.

### 6.1 DEFINITIONS

A neoplasm is a “new growth” composed of cells, originally derived from normal tissues, that have undergone heritable genetic changes allowing them to become relatively unresponsive to normal growth controls and to expand beyond their normal anatomic boundaries. Other common terms for neoplasms describe their clinical appearance or behavior: tumor (“swelling”) and cancer (“crab”). Although the terms *neoplasm* and *tumor* may refer to benign or malignant growths, the term *cancer* always denotes a malignant growth. Oncology is the study of neoplasia; the term is derived from the Greek word *oncos* (“tumor”).

Benign tumors do not invade surrounding tissue or spread to new anatomic locations within the body; thus these tumors are usually curable and are rarely responsible for the death of the host. Malignant tumors, if left untreated, will invade locally, may spread by metastasis (“change of place”), and will ultimately kill the host. Interestingly, tumors of the nervous system very rarely metastasize; however, many of these tumors are notably invasive and kill their hosts, thus the tumors are malignant.

With the recognition that tumor development is a stepwise process, potentially preneoplastic changes have assumed new diagnostic and clinical significance. These changes include hyperplasia (increased cell number in a tissue), metaplasia (transformation of one differentiated cell type into another), and dysplasia (abnormal pattern of tissue growth) (Fig. 6-1). Hyperplasia, which is an increase in the number of cells in a tissue, should be distinguished from hypertrophy, which is an increase in individual cell size rather than number. Metaplasia is seen most commonly in epithelial tissue. In several species of animals, vitamin A deficiency is characterized by squamous metaplasia of respiratory and digestive epithelium. Dysplasia usually refers to disorderly arrangement of cells within epithelium. In general, preneoplastic changes are reversible. They arise in response to physiologic demands, injury, or irritation and resolve with the removal of the inciting factor. For example, epidermal hyperplasia is a normal part of wound repair, and skeletal muscle hypertrophy is an adaptive response to increased workload. Premeoplastic changes often indicate an increased risk for neoplasia in the affected tissue, and preneoplastic lesions may themselves progress to neoplasia. The terms *dysplasia* and *metaplasia* can be applied to tumors to describe changes that persist during the transition from preneoplasia to neoplasia; however, the terms *hyperplasia* and *hypertrophy* are not appropriate in descriptions of true neoplasms.

### 6.2 NOMENCLATURE

Most tumors appear to consist of a single cell type, and the name of the neoplasm reflects the cell type (mesenchymal or epithelial) from which the tumor is presumed to arise.

### 6.2.1 MESENCHYMAL TUMORS

Mesenchymal tumors arise in cells of embryonic mesodermal origin. Benign tumors originating from mesenchymal cells are usually named by adding the suffix *-oma* to the name of the cell of origin. Thus a lipoma is a benign tumor derived from a lipocyte ("fat cell") (Fig. 6-2, A), and a fibroma is a benign tumor of fibroblast origin. A malignant tumor of mesenchymal origin is a sarcoma ("fleshy growth"). A prefix or modifier indicates the tissue of origin. For instance, a liposarcoma is a malignant tumor of lipocyte origin (Fig. 6-2, B), and a fibrosarcoma is a tumor composed of malignant fibroblasts. The cells comprising the hematopoietic system are mesenchymal. Tumors arising from circulating blood cells or their precursors are termed leukemias ("white blood"); neoplastic hematopoietic cells are usually found in large numbers in the blood stream (Fig. 6-3), although they may also form solid tumor masses.

253

254

**Fig. 6-1 Preneoplastic changes that may precede tumor emergence.**

Preneoplastic changes in tissues include alterations in cell number, size, and organization. Some of these terms can also be applied to neoplastic tissues, as indicated. In this example, preneoplastic changes are illustrated in simple cuboidal epithelium, although such changes may also occur in other epithelial and mesenchymal cell types. (Redrawn with permission from Dr. D.F. Kusewitt, College of Veterinary Medicine, The Ohio State University.)

**Fig. 6-2 Comparison of benign and malignant tumors of lipocyte origin, dog.** **A**, The benign lipoma is composed of mature fat cells indistinguishable from normal cells. H&E stain. **B**, The liposarcoma consists of poorly differentiated cells, many of which do not have the morphologic features characteristic of lipocytes H&E stain. (**A and B**, Courtesy College of Veterinary Medicine, The Ohio State University.)

### 6.2.2 EPITHELIAL TUMORS

All of the three embryonic cell layers—endoderm, mesoderm, and ectoderm—can give rise to epithelial tissue and to tumors derived from this tissue. Terms for both benign and malignant epithelial tumors are frequently modified by prefixes or adjectives describing their appearance or the response they elicit in surrounding tissue. For instance, the adjective “squamous” is applied to an epithelial neoplasm that demonstrates squamous differentiation.

Benign tumors that arise from glandular epithelium are called adenomas, whatever their microscopic appearance. However, the term is also applied to many tumors that are derived from nonglandular epithelial tissues but that have a tubular appearance, such as renal adenomas. The term *papilloma* refers to a benign exophytic growth arising from an epithelial surface, whereas a polyp is a grossly visible, benign epithelial tumor projecting from a mucosal surface (Fig. 6-4).

All malignant tumors of epithelial origin are termed carcinomas (“cancers”). The general term *carcinoma* may be further modified to indicate the organ of origin, as in hepatocellular carcinoma. The prefix *adeno-* indicates a glandular pattern of tumor growth. Adenocarcinomas may be described as papillary, tubular, or cystic. Carcinomas and adenocarcinomas that stimulate the formation of abundant collagen in surrounding connective tissue (desmoplasia) may be termed scirrhous. The neoplastic epithelial cells of mucinous carcinomas and adenocarcinomas produce abundant mucin. Carcinoma in situ is a preinvasive form of carcinoma that remains within the epithelial structure from which it arises and does not penetrate the basement membrane to enter the stroma.

254

255

Fig. 6-3 **Acute lymphoid leukemia, peripheral blood, dog.** The peripheral blood smear contains numerous neoplastic large lymphocytes. Flow cytometry identified these cells as B lymphocytes. The white blood cell count of this animal was 293,000 leukocytes per  $\mu\text{L}$ . Wright's stain. (Courtesy Dr. M.L. Wellman, College of Veterinary Medicine, The Ohio State University.)

Fig. 6-4 **Polyp, small intestine, mouse.** The neoplastic growth arises from the mucosa and extends into the lumen of the intestine. There is no invasion of the intestinal wall. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

**Fig. 6-5 Mixed mammary tumor, mammary gland, dog.** Mixed mammary tumors of dogs contain both epithelial structures (*arrow*) and mesenchymal elements, such as cartilage and bone (*arrowhead*). H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

### 6.2.3 UNDIFFERENTIATED TUMORS

The appearance of some malignant tumors gives no clue to their cell of origin; thus they are termed undifferentiated neoplasms.

### 6.2.4 MIXED TUMORS

Mixed tumors contain multiple cell types derived from a single or multiple germ layers. Mixed tumors are believed to arise from a single pluripotent or totipotent cell capable of differentiating into a variety of more mature cell types. Teratomas and teratocarcinomas arise from totipotent germ cells; thus they contain tissue derived from all embryonic cell layers and consist of a bizarre mixture of adult and embryonic tissue types. The mixed mammary gland tumor of dogs is generally considered a mixed tumor. A mixed mammary tumor is composed of a variable admixture of neoplastic epithelial elements (luminal epithelium and myoepithelium) and mesenchymal elements (fibrous connective tissue, fat, cartilage, and bone) (Fig. 6-5).

### 6.2.5 TUMORLIKE LESIONS

Hamartomas are disorganized but mature mesenchymal or epithelial tissues found in their normal anatomic location. Many of the hamartomas identified in animals consist of abnormal proliferations of blood vessels. Hamartomas apparently represent the result of aberrant differentiation rather than true neoplasia, and their

255

256

## Pathologic Basis of Veterinary Disease, 4th Edition

---

behavior is completely benign. Choristomas are composed of normal mature tissue located at an ectopic site. An example is the dermoid, a mass consisting of mature skin and its appendages, which may be found in a variety of unusual sites, including the cornea.

### 6.3 VETERINARY NOMENCLATURE

In [Table 6-1](#), the names of common benign neoplasms in animals and their malignant counterparts are shown. The names given are those commonly employed in veterinary medicine. The terms used by veterinary pathologists to describe tumors in animals may differ from the terms used by medical pathologists to describe human tumors. This is partly because conventional usage plays an important role in tumor nomenclature; thus tumor nomenclature may be dictated by historical precedent rather than by logic. Moreover, attempts to standardize diagnostic terms for tumors in veterinary medicine have lagged far behind such efforts in the medical arena. A significant difference between veterinary and human nomenclature is that a benign tumor arising from melanocytes is termed a “benign melanoma” or “melanocytoma” by veterinary pathologists and a “nevus” by medical pathologists. Medical pathologists reserve the term *melanoma* for a malignant tumor of melanocyte origin, whereas veterinary pathologists term such tumors “malignant melanomas.”

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 6-1 Tumor Nomenclature

	ORIGIN	Tissue of Origin	Cell of Origin	Benign	Malignant	
MESENCHYMAL	Connective tissue and related tissue	Fibrous connective tissue	Fibroblast	Fibroma	Fibrosarcoma	
		Fat	Adipocyte	Lipoma	Liposarcoma	
		Cartilage	Chondrocyte	Chondroma	Chondrosarcoma	
		Bone	Osteoblast	Osteoma	Osteosarcoma	
		Endothelium and related tissue	Blood vessel	Vascular endothelium	Hemangioma	Hemangiosarcoma
			Lymphatic vessel	Lymphatic endothelium	Lymphangioma	Lymphangiosarcoma
		Synovium	Synovial lining cell	Synovioma	Synovial sarcoma	
		Mesothelium	Mesothelial cell		Mesothelioma	
		Meninges	Meningeal connective tissue cell	Meningioma	Malignant meningioma	
		Ovary	Modified mesothelium	Adenoma	Adenocarcinoma	
	Hematopoietic and lymphoid tissue	Lymphoid tissue	Lymphocytes	*	Lymphoma	
		Bone marrow	Leukocytes and erythrocytes	*	Leukemia	
		Connective tissue	Mast cell	Mast cell tumor	Malignant mast cell tumor	
	Muscle	Smooth muscle	Histiocytes Smooth muscle cell	Histiocytoma Leiomyoma	Malignant histiocytosis Leiomyosarcoma	
		Skeletal muscle	Skeletal muscle cell	Rhabdomyoma	Rhabdomyosarcoma	
EPITHELIAL	Lining or covering epithelia	Skin	Squamous epithelial cell	Papilloma	Squamous cell carcinoma	
			Adnexal cells	Adenoma	Adenocarcinoma	
			Melanocyte	Benign melanoma	Malignant melanoma	
		Upper alimentary tract	Squamous epithelial cell	Papilloma	Carcinoma	
		Lower alimentary tract	Columnar epithelium	Adenoma	Adenocarcinoma	
		Upper respiratory tract	Columnar epithelium	Adenoma	Adenocarcinoma	
		Lung	Columnar epithelium of bronchi and bronchioles	Adenoma	Carcinoma	

## Pathologic Basis of Veterinary Disease, 4th Edition

NERVOUS TISSUE	Solid epithelial organs	Urinary tract	Alveolar epithelium	Adenoma	Adenocarcinoma
			Transitional epithelium	Papilloma	Transitional cell carcinoma
			Columnar epithelium	Uterine polyp	Endometrial carcinoma
		Lining of glands or ducts	Prostate, thyroid, bile ducts of liver, etc.	Adenoma	Endometrial adenocarcinoma
					Adenocarcinoma
		Glands	Pancreas, salivary gland, etc.	Adenoma	Adenocarcinoma
		Liver	Hepatocyte	Hepatoma	Hepatocellular carcinoma
		Kidney	Renal tubular cell	Renal tubular adenoma	Renal cell carcinoma
		Testicle	Sertoli cell	Sertoli cell tumor	Sertoli cell tumor
			Interstitial cell	Interstitial cell tumor	
		Ovary	Germ cell	Seminoma	Seminoma

### 6.4 TUMOR CHARACTERISTICS

257

#### 6.4.1 BENIGN VERSUS MALIGNANT TUMORS

The most important distinction between benign and malignant tumors is that malignant tumors are able to invade locally and metastasize systemically, but benign tumors are not. The invasive capabilities of malignant tumors are associated with enhanced tumor cell motility, increased production of proteases, and altered tumor cell adhesion characteristics. Although benign tumors are ultimately distinguished from their malignant counterparts based on invasiveness, a variety of morphologic and behavioral features are generally considered

## Pathologic Basis of Veterinary Disease, 4th Edition

to predict the potential for malignant behavior (Table 6-2). Although both benign and malignant tumors are composed of proliferating cells, malignant tumors have essentially unlimited replicative potential. The tumors are relatively independent of exogenous growth stimulatory molecules and are insensitive to growth inhibitory signals from their environment. Moreover, malignant cells are better able than benign cells to evade programmed cell death (apoptosis) and to escape the host's cytotoxic immune response. Compared with benign tumors, malignant tumors stimulate marked angiogenesis (the formation of new blood vessels), thus assuring adequate tumor nutrition.

257

258

Table 6-2 Comparisons between Benign and Malignant Tumors

Characteristic	Benign	Malignant
Differentiation	Well-differentiated appearance Structure similar to tissue of origin Little or no anaplasia	Usually some lack of differentiation Structure often atypical Variable degree of anaplasia
Growth rate	Slow, progressive expansion Rare mitotic figures Normal-appearing mitotic figures	Slow to rapid growth; erratic growth rate Mitotic figures often numerous Mitotic figures sometimes abnormal
Local invasion	No invasion Cohesive and expansile growth Capsule often present	Local invasion Infiltrative growth Usually no capsule
Metastasis	No metastasis	Frequent metastasis (definitive criterion for malignancy)

Because some benign tumors evolve into malignant neoplasms and some malignant tumors develop increasingly aggressive behavior over time (a process termed malignant progression), tumors may be graded to reflect where they lie on the continuum from benign to highly malignant and/or staged to indicate the extent of tumor spread. Together the grade and stage of the tumor indicate the risk the tumor poses to the host and help determine therapeutic strategy. It should be noted, however, that many benign tumors, such as equine sarcoids, have little or no malignant potential and rarely if ever evolve into malignant tumors.

### 6.4.2 DIFFERENTIATION

#### 6.4.2.1 HALLMARKS OF DIFFERENTIATION

##### 6.4.2.1.1 Morphology

Each normal, fully differentiated, mature tissue type has a characteristic gross and microscopic appearance that varies little from individual to individual of a species. Neoplastic tissues lose these differentiated features of cellular morphology and organization to a variable extent. In general, malignant tumors appear less differentiated than benign tumors. Loss of morphologic hallmarks of tissue maturity is often accompanied by loss of functional capacity and development of aggressive behavior.

Neoplastic cells often show considerable morphologic variability compared with the normal tissue from which they are derived. Tumor cells, especially malignant tumor cells, may exhibit anaplasia (cellular atypia). Anaplastic cells are poorly differentiated cells that exhibit notable cellular and nuclear pleomorphism (variation in size and shape). In some tumors, bizarre tumor giant cells are seen (Fig. 6-6). Nuclei may exhibit extreme variability in number, size, shape, chromatin distribution, and nucleolar size and number (Fig. 6-7). Anaplastic nuclei are often hyperchromatic (darkly staining) because of increased DNA content; are disproportionately large relative to cell size, resulting in an increased

## Pathologic Basis of Veterinary Disease, 4th Edition

---

nuclear:cytoplasmic ratio; and have prominent nucleoli. Mitotic figures in tumor cells may be numerous. Many of the nuclear changes seen in neoplastic cells reflect the frequent cell division, chromosomal abnormalities, and active metabolic state that characterize these cells.

**Fig. 6-6 Rhabdomyosarcoma, skeletal muscle, chicken.**

Rhabdomyosarcomas often contain bizarre tumor giant cells such as the cell indicated by the arrow. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

Neoplastic cells often exhibit loss of characteristic cytoplasmic as well as nuclear features. For instance, poorly differentiated mast cell tumors often lack the prominent cytoplasmic granules that are a hallmark of normal mast cells (Fig. 6-8). Special stains or immunohistochemistry may be able to highlight some characteristic morphologic feature retained in at least a subpopulation of tumor cells. As an example, characteristic granules may be revealed in some cells of feline and canine mast cell tumors by staining with toluidine blue or Giemsa. Many tumor cells have noticeably basophilic cytoplasm as a result of the presence of large numbers of ribosomes required for rapid cell growth and frequent cell division.

258

259

Fig. 6-7 **Anaplastic sarcoma, heart, mouse.** This tumor exhibits marked nuclear pleomorphism and has a fairly high mitotic index. The inset shows a notably abnormal mitotic figure. H&E stain. (**Figure and Inset**, Courtesy College of Veterinary Medicine, The Ohio State University.)

Fig. 6-8 **Mast cell tumor, skin, cat.** With H&E staining, hallmark mast cell granules are not visible. To see these granules, the section must be stained with a metachromatic stain such as toluidine blue or giemsa. Note the very large single nucleolus and marginated chromatin in the neoplastic cells. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In tumors, normal tissue organization is usually lost to some extent. Increasing loss of normal architecture in tumors correlates with increasing independence of tumor cells from their surrounding tissue. As an example, lymphomas arising in lymph nodes often consist of solid sheets of neoplastic cells that partially or completely efface normal lymph node architecture (Fig. 6-9). In tissue that normally undergoes continual renewal, such as the skin and oral mucosa, the normal maturation sequence may be altered. Thus in squamous cell carcinomas, the orderly morphologic progression from basal cell layer to fully keratinized stratum corneum may not be seen (Fig. 6-10).

**Fig. 6-9 Lymphoma (lymphosarcoma), lymph node, dog.** The normal lymph node architecture has been completely effaced by solid sheets of neoplastic lymphocytes. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Fig. 6-10 **Squamous cell carcinoma, tongue, cat.** The orderly pattern of epidermal maturation seen in normal oral mucosa is absent from this squamous cell carcinoma. An occasional “keratin pearl” (arrow) reveals the tissue of origin for this tumor. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

6.4.2.1.2

### Function

Loss of differentiated function frequently accompanies loss of differentiated morphology in tumors. Thus neoplastic cells arising from alveolar lining cells of the lung generally fail to perform normal respiratory functions and tumors of primitive germ cell origin do not form normal sperm or ova. Some aspects of normal function may be retained. Thyroid adenomas may continue to produce thyroid hormones and plasma cell tumors may secrete immunoglobulins. However, in the majority of cases, these functions are no longer regulated appropriately because the neoplastic cells have lost responsiveness to and dependence upon normal regulatory pathways. Thus thyroid adenomas may produce clinical hyperthyroidism, and plasma cell tumors may cause hypergammaglobulinemia.

259

260

6.4.2.1.3

### Behavior

Benign tumors are generally expansile and may compress adjacent tissue, whereas malignant tumors have invasive and in many instances metastatic capabilities. In malignant tumors, alterations in adhesion, motility, and protease production allow tumor cells to leave the tumor mass and penetrate surrounding tissue. Moreover, for malignant cells to invade and ultimately metastasize, they must become completely independent of local growth regulatory controls and acquire an independent blood supply. Acquisition of these features allows tumors to spread well beyond their ordinary anatomic niches.

### STEM CELLS AND DIFFERENTIATION

Most tumors are composed of cells that lack fully differentiated morphologic, functional, and behavioral characteristics. Furthermore, many neoplastic cells share some features with the embryonic cells that gave rise to the mature tissue in which the tumor originated. This similarity between embryonic and neoplastic cells may be accounted for in two different ways. First, normal mature cells may undergo dedifferentiation as they evolve into tumor cells, leading to the reemergence of more primitive characteristics. Second, tumors may arise from the small population of stem cells found in all adult tissue; such stem cells are required for normal tissue renewal. The appearance and behavior of the tumor that develops from a neoplastic stem cell is determined by the stage of differentiation at which the malignant phenotype is manifested; the neoplastic stem cell is said to have undergone maturation arrest at that stage of its development. The diversity of cell types that can arise from a single progenitor stem cell is limited by the differentiation potential of that cell.

Totipotent stem cells, such as embryonic stem cells, can give rise to all tissues of the body, whereas multipotent or pluripotent stem cells can give rise to a smaller variety of tissue types. The plasticity of most adult stem cells is generally considered to be relatively restricted. Leukemias provide excellent examples of neoplasms arising from stem cells. A leukemia almost always arises from a single hematopoietic stem cell that has undergone heritable genetic change. The progeny of this stem cell all exhibit the same genetic change, although the cell type and degree of differentiation of the progeny may vary. Thus in myelogenous leukemia, a neoplastic multipotential stem cell may give rise to a combination of leukemic cells of the granulocytic, monocytic, and erythroid series (Fig. 6-11). The concept of a stem cell origin for cancer explains not only the embryonic characteristics of neoplastic cells, but also the success of treatment strategies that use differentiating agents, such as retinoids (vitamin A derivatives used to induce maturation of some human leukemia cells).

**Fig. 6-11 Myelomonocytic leukemia, peripheral blood, dog.** In this unusual case, leukemic cells of both monocytic (*arrowheads*) and granulocytic (basophil) (*arrow*) origin were present in peripheral blood. The animal had a marked leukocytosis (103,000 white blood cells per  $\mu\text{L}$ ) and thrombocytopenia. Wright's stain. (Courtesy Dr. M.J. Burkhard, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 6.4.3 PROLIFERATION

#### 6.4.3.1 THE CELL CYCLE

The cell cycle consists of  $G_1$  (presynthetic), S (DNA synthesis),  $G_2$  (premitotic), and M (mitotic) phases (Fig. 6-12). Quiescent cells are in a physiologic state called  $G_0$ . In adult tissue, many cells reside in  $G_0$  and are unable to enter the cell cycle at all or do so only when stimulated by extrinsic factors.

#### 6.4.3.2 CONTROL OF NORMAL CELL PROLIFERATION AND TISSUE GROWTH\*

In adult tissues, the size of a cell population is determined by the relative rates of cell proliferation, differentiation, and death by apoptosis. Fig. 6-13 depicts these relationships and shows that increased cell numbers may result from either increased proliferation or decreased cell death.

260

261

**Fig. 6-12 Cell-cycle landmarks.** The figure shows the cell-cycle phases ( $G_0$ ,  $G_1$ ,  $G_2$ , S, and M), the location of the  $G_1$  restriction point, and the  $G_1$ /S and  $G_2$ /M cell-cycle checkpoints. Cells from labile tissues, such as the epidermis and the gastrointestinal (GI) tract, may cycle continuously; stable cells, such as hepatocytes, are quiescent but can enter the cell cycle; permanent cells, such as neurons and cardiac myocytes, have lost the capacity to proliferate. (Modified from Pollard TD, Earnshaw WC: *Cell biology*, Philadelphia, 2002, Saunders.)

**Fig. 6-13 Mechanisms regulating cell populations.** Cell numbers can be altered by increased or decreased rates of stem cell input, by cell death due to apoptosis, or by changes in the rates of proliferation or differentiation. (Modified from McCarthy NJ, Smith CA, Williams GT: *Cancer Metastasis Rev* 11:157-178, 1992.)

### 6.4.3.2.1

#### Proliferation

Cell proliferation is largely controlled by signals (soluble or contact-dependent) from the microenvironment that either stimulate or inhibit cell proliferation. An excess of stimulators or a deficiency of inhibitors leads to net growth and, in the case of cancer, uncontrolled growth. Although accelerated growth can be accomplished by shortening the cell cycle, the most important mechanism of growth is the conversion of resting or quiescent cells into proliferating cells by making the cells enter the cell cycle. Both the recruitment of quiescent cells into the cycle and cell-cycle progression require stimulatory signals to overcome normal physiologic blocks to cell proliferation. Cell proliferation can be stimulated under both physiologic and pathologic conditions. The proliferation of mammary epithelium under hormonal stimulation during lactation is an example of physiologic proliferation. Pathologic conditions, such as tissue injury, cell death, and mechanical alterations, also stimulate cell proliferation. Excessive physiologic stimulation may create pathologic conditions, such as enlargement of the thyroid as a consequence of increased serum levels of thyroid-stimulating hormone.

261

262

## Pathologic Basis of Veterinary Disease, 4th Edition

---

6.4.3.2.2

### Differentiation

Differentiation also impacts the size of a cell population and its proliferative potential. For example, myocytes and neurons are terminally differentiated cells (i.e., they are at an end stage of differentiation and are not capable of replicating). In some adult tissues, such as liver and kidney, differentiated cells are normally quiescent but are able to proliferate when necessary. In proliferative tissue, such as bone marrow and the epithelia of the skin and gut, the mature cells are terminally differentiated, short-lived, and incapable of replication, but they may be replaced by new cells arising from stem cells. Thus in such tissues there is a homeostatic equilibrium between the proliferation of stem cells, their differentiation, and the death of fully differentiated cells.

6.4.3.2.3

### Apoptosis

Apoptosis, sometimes called “programmed cell death,” is a physiologic process required for tissue homeostasis. In proliferative tissue, such as gut epithelium, terminally differentiated and functionally effete cells undergo apoptosis and are thus removed from the cell population. Apoptosis can also be induced by a variety of pathologic stimuli. Apoptosis may occur in response to withdrawal of survival factors from the cell environment or by binding of death factors, such as Fas ligand and tumor necrosis factor (TNF)- $\alpha$ , to cell surface receptors. Hypoxia and lack of essential nutrients may end in apoptosis. DNA damage may also induce apoptosis; in this case, apoptosis is triggered by p53. Apoptosis may be stimulated by the activity of cytotoxic immune cells, including T lymphocytes and natural killer (NK) cells. Signals for apoptosis activate a variety of signaling pathways, many of which ultimately result in the release of cytochrome C from mitochondria. The final effectors of apoptosis are the caspases, intracellular proteases that selectively destroy cellular organelles and degrade genomic DNA into nucleosome-sized fragments. The morphologic hallmarks of apoptosis include margination of chromatin, condensation and fragmentation of the nucleus, and condensation of the cell with preservation of organelles. Ultimately the cell breaks into membrane-bound apoptotic bodies that are engulfed by surrounding cells without stimulating an inflammatory response ([Fig. 6-14](#)).

\* Portions of this section are from Kumar V, Abbas A, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.

6.4.3.3

### TISSUE PROLIFERATIVE ACTIVITY

Tissue may be composed primarily of quiescent cells in  $G_0$ , but most mature tissue contains some combination of continuously dividing cells, terminally differentiated cells, stem cells, and quiescent cells that enter the cell cycle. Stem cells have special properties, which were described previously. The tissues of the body may be divided into three groups on the basis of their proliferative activity.

**Fig. 6-14 Lymphoma, apoptotic lymphoma cells, spleen, mouse.** The light microscopic appearance of apoptosis is characterized by condensation and fragmentation of nuclei (*arrows*), cell shrinkage, engulfment of apoptotic bodies by surrounding cells, and lack of inflammation. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

### 6.4.3.3.1

#### Continuously Dividing Tissues (Labile Tissues)

In continuously dividing tissues (also called labile tissues), cells proliferate throughout life, replacing those that are lost. These tissues include surface epithelia, such as stratified squamous surfaces of the skin, oral cavity, vagina, and cervix; the lining mucosa of all the excretory ducts of the glands of the body (e.g., salivary glands, pancreas, and biliary tract); the columnar epithelium of the gastrointestinal tract and uterus; the transitional epithelium of the urinary tract; and cells of the bone marrow and hematopoietic tissue. In most of these tissues, mature cells are derived from stem cells, which have an unlimited capacity to proliferate and whose progeny may differentiate into a variety of mature cell types.

### 6.4.3.3.2

#### Quiescent Tissues (Stable Tissues)

Quiescent (or stable) tissues normally have a low level of replication; however, cells from these tissues can undergo rapid division in response to stimuli and are thus capable of reconstituting the tissue of origin. They are considered to be in the  $G_0$  stage of the cell cycle but can be stimulated to enter  $G_1$ . In this category are the parenchymal cells of the liver, kidneys, and pancreas; mesenchymal cells, such as fibroblasts and smooth muscle; vascular endothelial cells; and resting lymphocytes and other leukocytes. The regenerative capacity of stable cells is best exemplified by the ability of the liver to regenerate after partial hepatectomy and after acute chemical injury. Fibroblasts, endothelial cells, smooth muscle cells,

262

263

## Pathologic Basis of Veterinary Disease, 4th Edition

---

chondrocytes, and osteocytes are quiescent in adult mammals but proliferate in response to injury. Fibroblasts in particular may proliferate extensively.

6.4.3.3.3

### Nondividing Tissues (Permanent Tissues)

Nondividing (permanent) tissues contain cells that have left the cell cycle and cannot undergo mitotic division in postnatal life. To this group belong neurons, and skeletal and cardiac muscle cells. If neurons in the central nervous system are destroyed, the tissue is generally replaced by the proliferation of the central nervous system supportive elements—the glial cells. However, recent results demonstrate that limited neurogenesis from stem cells may occur in adult brains. Although mature skeletal muscle cells do not divide, skeletal muscle does have some regenerative capacity, through the differentiation of the satellite cells that are attached to the endomysial sheaths. If the ends of severed muscle fibers are closely juxtaposed, muscle regeneration in mammals can be excellent, but this is a condition that can rarely be attained under practical conditions. Cardiac muscle has very limited, if any, regenerative capacity, and extensive injury to the heart muscle, as may occur in myocardial infarction, is followed by scar formation.

**Fig. 6-15 Biology of solid tumor growth.** The center panel illustrates clonal evolution of a tumor and generation of tumor-cell heterogeneity. New subclones arise from descendents of the original transformed cell. With progressive growth, the tumor mass becomes enriched for those variants that are more adept at evading host defenses and are likely to be more aggressive. The left panel shows the corresponding stages of tumor progression, and the right panel depicts minimal estimates of tumor-cell doublings that precede the formation of a clinically detectable tumor mass. It is evident that by the time a solid tumor is detected, it has already completed a major portion of its life cycle, as measured by population doublings. The maximum tumor size compatible with life depends to some extent on the species affected. (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

As illustrated in Fig. 6-15, the latent period for a tumor is the time before a tumor becomes clinically detectable. The smallest clinically detectable mass is about 1 cm in diameter and contains about  $10^9$  cells. To form a tumor that size, a single transformed cell must undergo about 30 rounds of cell division, if all the progeny remain viable and capable of replication. Thus, by the time most tumors become clinically evident, they have probably been developing in the host for many years. However, once tumors reach a clinically detectable size, their growth may appear to be very rapid, because only 10 doubling cycles are required to convert a 1-g tumor into a 1-kg tumor. In fact, volume doubling times for tumors vary considerably, depending upon the rate at which tumor cells divide, the fraction of tumor cells that are replicatively competent, and the rate at which tumor cells die. In general, benign neoplasms grow more slowly than malignant tumors, although there is considerable variation among tumors. Moreover, tumors may grow erratically depending on their blood supply, the effect of extrinsic growth-regulating factors such as hormones, the efficacy of the host immune response, and the emergence of subpopulations of particularly aggressive tumor cells.

The mitotic index is usually defined as the number of cells in a microscopic field that contain condensed chromosomes and lack nuclear membranes (Fig. 6-16). Such cells are interpreted as being actively dividing, and the mitotic index of a tumor is considered to indicate its malignant potential. However, the mitotic index can be misleading. The fraction of tumor cells observed to be in mitosis depends not only on the number of cells undergoing mitosis but also on the length of time required to complete the process. In tumor cells, the time required for completion of the cell cycle is generally as long as or even longer than for normal cells. Mitotic figures may persist in cells unable to complete cell division and abnormal mitotic figures may be seen.

**Fig. 6-16 Lymphoma, mitotic figures, lymph node, mouse.** The arrows indicate mitotic figures. This tumor has a high mitotic index. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

6.4.3.4.1

### Proliferative Potential

Essentially unlimited proliferative potential is a hallmark of neoplasia, especially of malignant neoplasms. Unlike normal cells, many tumor cells are immortal. This immortality is due to a combination of the alterations discussed later. In general, neoplastic cells escape normal limits on cell division, become independent of external growth stimulatory and inhibitory factors, and lose their susceptibility to apoptotic signals. This results in an imbalance between cell production and cell loss and a net increase in tumor size. However, it should be noted that the growth of a tumor is not completely exponential. A proportion of tumor cells is continually lost from the replicative pool because of irreversible cell-cycle arrest, differentiation, and death ([Fig. 6-17](#)).

6.4.3.4.2

### Telomerase

Because the DNA replication machinery is unable to duplicate the extreme ends of DNA templates, the telomeres that form the ends of chromosomes are shortened at each cell division. Embryonic cells express telomerase, a riboprotein enzyme that allows telomeres to be replicated and even expanded; however, most adult cells do not express this protein and their telomeres shrink with each round of cell division. Very short telomeres are incompatible with continued cell division. Many neoplastic cells regain the ability to produce telomerase and thus to replicate their telomeres. Reexpression of telomerase appears to play an important role in tumor cell immortality.

6.4.3.4.3

### Cell Cycle

Many adult cell types are not mitotically active. These cells have exited the G<sub>1</sub> phase of the cell cycle and reside in G<sub>0</sub>. Moreover, in response to DNA damage, even actively dividing normal cells undergo cell-cycle arrest, usually at one of several cell-cycle checkpoints. Cell-cycle arrest is initiated by the multifunctional tumor suppressor gene product p53 and gives the cell time to repair DNA damage. Many neoplastic cells no longer respond to extrinsic or intrinsic signals directing them into G<sub>0</sub> and no longer express functional p53. Thus the cells move continuously through the cell cycle. Moreover, because the tumor cells do not undergo cell-cycle arrest following DNA damage, they progressively accumulate potentially mutagenic DNA damage ([Fig. 6-18](#)).

264

265

## Pathologic Basis of Veterinary Disease, 4th Edition

**Fig. 6-17 Schematic representation of tumor growth.** As the cell population expands, a progressively higher percentage of tumor cells leave the replicative pool by reversion to  $G_0$ , differentiation, and death. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

6.4.3.4.4

### Growth Modulation

For homeostasis to be maintained, normal cells must engage in a continual dialogue with their environment. There is a constant exchange of information among cells via soluble mediators, including growth stimulatory factors, growth inhibitory factors, and hormones. These soluble mediators tightly control the growth of nonneoplastic cells. Neoplastic cells, on the other hand, often lose both their dependence upon extrinsic growth stimulatory substances and their susceptibility to growth inhibitory signals from their environment. The mechanisms by which this occurs are discussed later. The end result is that tumor cells are no longer responsive to the needs of the organism as a whole and develop the capacity to drive their own replication.

6.4.3.4.5

### Apoptosis

Although virtually all normal cells in the body can undergo apoptosis (programmed cell death) in response to appropriate physiologic signals, many cancer cells acquire resistance to apoptosis. This blocks a major route of tumor cell loss and enhances the overall growth rate of the tumor. Many tumor cells circumvent apoptosis by functional inactivation of the p53 gene, thus removing a key proapoptotic molecule. Additionally, tumor cells may constitutively activate survival signaling pathways, rendering the cells independent of exogenous survival factors. Finally, tumor cells may develop mechanisms for inactivating death factor signaling pathways, thus evading apoptosis in response to homeostatic signals from the cellular environment.

**Fig. 6-18 Schematic representation of the cell cycle.** Many normal cells reside in  $G_0$ , a nonreplicative state. When they do enter the proliferative cycle, they can arrest at cell-cycle checkpoints at the  $G_1$ -S and  $G_2$ -M boundaries in response to a variety of stimuli, including DNA damage. In contrast, tumor cells spend little time in  $G_0$  and often do not undergo cell-cycle arrest in response to DNA damage or lack of extrinsic growth stimuli. (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 6.4.3.5 GENOMIC INSTABILITY

Evolving genomic instability is a hallmark of cancer. Many tumor cells fail to undergo cell-cycle arrest or apoptosis in response to DNA damage. They produce long and unstable telomeres subject to breakage, they lose the ability to carry out effective DNA repair, they demonstrate aberrant DNA methylation, and they exhibit increased rates of gene amplification, recombination, conversion, and transposition. These factors contribute to an increased rate of mutation and chromosomal aberration in neoplastic cells. Ultimately, this genomic instability results in aneuploidy, a chromosome complement that is not a simple multiple of the haploid chromosome content, or polyploidy, a chromosome complement more than twice the haploid chromosome number. The karyotypes of cancer cells may thus be notably abnormal and unstable. As a rule, increasing aneuploidy is correlated with increasingly malignant behavior. Genomic instability will be discussed in more detail later in the chapter.

### 6.5 TUMOR EVOLUTION

#### 6.5.1 STEPWISE TUMOR DEVELOPMENT

Neoplasms develop as the result of multiple genetic and epigenetic changes that occur over a relatively long time course. It is the cumulative effect of these alterations that create a tumor. The stepwise evolution of tumors has been studied most thoroughly in carcinomas. There are several types of carcinoma that develop in an

## Pathologic Basis of Veterinary Disease, 4th Edition

---

orderly and predictable fashion. For instance, squamous cell carcinoma arises from the epithelium of the eyelid in many species of animals, including cattle, horses, cats, and dogs. In all species, these tumors develop through the same sequence of steps: epidermal hyperplasia, carcinoma in situ, and invasive carcinoma. Extensive studies of experimentally induced squamous cell carcinomas in the skin of mice have revealed a similar morphologic pattern of tumor evolution ([Fig. 6-19](#)) and have led to a detailed model of stepwise carcinoma development as described in the following section ([Fig. 6-20](#)).

265

Fig. 6-19 **Development of squamous cell carcinoma in the skin of a hairless mouse exposed to ultraviolet radiation.** **A**, A focus of epidermal hyperplasia (*arrow*) is the earliest lesion seen. **B**, This develops into a papilloma, a benign exophytic papillary growth that is highly keratinized and does not penetrate into the dermis. **C**, As the papilloma undergoes conversion into a malignant squamous cell carcinoma, it begins to invade the dermis and to lose the regular pattern of epithelial differentiation. **D**, A fully developed squamous cell carcinoma has lost most differentiated characteristics and extends deep into the dermis. Only a few keratin “pearls” (*arrow*) indicate the origin of this tumor from the epidermis of the skin. All figures were taken at the same magnification. H&E stain. (*A through D*, Courtesy Dr. T.M. Oberyszyn, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

6.5.1.1

### INITIATION

The first step is initiation, the introduction of irreversible genetic change into basal cells of the skin by the action of a mutagenic initiating agent or initiator. Initiators are chemical or physical carcinogens that damage DNA. Mutation induction requires not only the introduction of a DNA lesion, but also mispairing of the DNA lesion during subsequent DNA replication to produce an altered complementary DNA strand. Thus at least a single round of DNA replication is necessary for fixation of the genetic change to occur. Initiated cells appear morphologically normal and may remain quiescent for many years. However, these cells harbor mutations that provide them with a growth advantage under special conditions. For instance, the initiated cells may respond more vigorously to mitogenic signals or be more resistant to apoptosis-inducing stimuli than their neighbors.

6.5.1.2

### PROMOTION

The second stage of tumor development is promotion. Promotion refers to the outgrowth of initiated cells in response to selective stimuli. Most of these selective stimuli, termed promoting agents or promoters, drive proliferation. For example, the skin irritant croton oil is an effective skin tumor promoter. In general, promoters are not mutagenic; instead, they alter gene expression in initiated and uninitiated cells to create an environment in which initiated cells have a growth advantage. Because promoters are nonmutagenic, their effects are usually reversible, and some papillomas can actually undergo regression. What emerges at the end of the promotion phase of tumor development is a papilloma, a benign tumor.

6.5.1.3

### PROGRESSION

The final stage of tumor development, progression, includes the conversion of a benign tumor to an increasingly malignant tumor and, ultimately, to a metastatic tumor. Malignant conversion represents an irreversible change in the nature of the developing tumor. Progression is a complex and poorly understood process involving both genetic and epigenetic changes in tumor cells and their environment that select for increasingly malignant clones of tumor cells. Karyotypic instability in tumor cells and increasing tumor cell heterogeneity are hallmarks of progression.

6.5.2

### TUMOR HETEROGENEITY AND CLONAL SELECTION

Most tumors are believed to be of clonal origin (i.e., they are ultimately derived from a single transformed cell). Tumor cell heterogeneity is generated during the course of tumor growth by the progressive accumulation of heritable changes in tumor cells (Fig. 6-15). With each new genetic alteration, the progeny of the genetically altered tumor cell constitute a subclone of tumor cells. The generation of subclones is fostered by the marked genetic instability of tumor cells compared with normal cells. Successful subclones are those that have a high proliferative rate, are able to evade the host immune response, can stimulate the development of an independent blood supply, are independent of exogenous growth factors, and are able to escape from the primary tumor and spread to distant sites. These characteristics give successful subclones a selective advantage over other subclones of cells within the tumor. A tumor subclone with a selective advantage will eventually predominate.

266

267

**Fig. 6-20 Illustration of stepwise tumor development.** Initiated cells have irreversible genetic damage. In the presence of a promoter, these initiated cells expand to form a preneoplastic lesion or benign tumor. With further genetic and epigenetic alterations, a malignant tumor emerges from a subclone of cells within the benign precursor lesion. (Redrawn with permission from Dr. D.F. Kusewitt, College of Veterinary Medicine, The Ohio State University.)

### 6.5.3 MOLECULAR CHANGES UNDERLYING TUMOR PROGRESSION

In a few well-studied tumor types, such as chemically induced skin tumors in mice and colonic carcinomas in humans, the stepwise molecular changes that underlie morphologic changes in the tumors have been determined. Many of these genetic changes are associated with proliferation, DNA repair, angiogenesis, and invasiveness, as detailed later.

### 6.6 TUMOR SPREAD

#### 6.6.1 FEATURES OF TUMOR SPREAD

Malignant tumors are often highly invasive. They do not respect anatomic boundaries, and they infiltrate adjacent normal tissue. Benign tumors, on the other hand, are generally expansile rather than infiltrative. The border between a benign tumor and adjacent tissue is usually distinct, and benign tumors of epithelial origin are often encapsulated (surrounded by a connective tissue capsule). Metastasis occurs when colonies of tumor cells take up residence at some distance from the parent tumor. Metastasis is the single most reliable hallmark of malignancy. Benign tumors do not metastasize. However, some malignant tumors, notably those of the central nervous system, are also nonmetastatic. Metastatic disease is believed to be responsible for 90% of human cancer deaths. Moreover, it is estimated that approximately 30% of solid cancers in humans have already metastasized by the time of initial diagnosis, greatly reducing the possibility of successful therapy. Cancer may

## Pathologic Basis of Veterinary Disease, 4th Edition

---

metastasize by seeding of the body cavities and surfaces (transcoelomic spread), by lymphatic spread, or by hematogenous spread.

### 6.6.2 PATHWAYS OF TUMOR METASTASIS

#### 6.6.2.1 TRANSCOELOMIC

When cancers arise on the surface of an abdominal or thoracic structure, they encounter few anatomic barriers to spread. Thus mesotheliomas may be confined to the abdominal or pleural cavities, but the tumor cells within these cavities readily spread to cover all visceral and parietal surfaces (Fig. 6-21). In both humans and dogs, ovarian adenocarcinomas preferentially spread transcoelomically. Although such tumors are rare in dogs, they are commonly encountered in women. Even in the absence of invasion into the underlying organs, tumors such as mesotheliomas and ovarian adenocarcinomas are extremely difficult to treat and are generally fatal.

#### 6.6.2.2 LYMPHATIC

In general, most carcinomas metastasize via the lymphatic system, although sarcomas may also employ this route of spread. The pattern of lymph node involvement is usually dictated by preexisting routes of regional lymphatic drainage. The lymph nodes closest to the tumor are usually colonized earliest and develop the largest metastatic tumor masses (Fig. 6-22). Thus adenocarcinomas of the intestine in all species usually metastasize first to the mesenteric lymph nodes and later to other lymph nodes within and outside the abdominal cavity. For many years, it was assumed that cancers spread in a stepwise manner from the primary site to regional lymph nodes, then to distant sites, such as the lung, and that regional lymph nodes actually represented a mechanical barrier to the spread of cancer. Thus removal of regional lymph nodes containing tumor tissue was believed to protect the patient from further spread of the tumor. However, regional lymph nodes may be bypassed as a result of natural, tumor-related, or treatment-induced anomalies in lymphatic drainage. More recent studies suggest that lymphatic spread does not occur in an orderly fashion and that metastasis to regional lymph nodes indicates that neoplastic disease has become widely systemic.

267

268

**Fig. 6-21 Mesothelioma, peritoneum of the abdominal cavity, dog.**  
Mesotheliomas spread extensively within body cavities, but rarely metastasize by lymphatic or hematogenous routes. Note in the figure that neoplastic mesothelial cells cover the serosal surfaces and form papillary fronds, but they do not infiltrate underlying tissue. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

Fig. 6-22 **Pancreatic carcinoma, metastatic, hepatic (portal) lymph node, dog.** Tumor cells (*T*) have almost completely replaced the normal architecture of the lymph node, except for a thin subcapsular rim of lymphocytes (*L*). The tumor was confirmed by immunohistochemistry to be a functional pancreatic islet  $\beta$ -cell carcinoma. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

Fig. 6-23 **Hemangiosarcoma, metastatic, lung, dog.** The multifocal (embolic) distribution of tumor nodules of relatively uniform size throughout the lung is characteristic of hematogenous metastasis. (Courtesy College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

6.6.2.3

### HEMATOGENOUS

Because lymphatic vessels connect with the vascular system, the distinction between lymphatic and hematogenous spread is somewhat artificial. However, sarcomas do tend to use the hematogenous route of spread more frequently than carcinomas. Tumors generally invade veins rather than do arteries because arterial walls are much thicker and more difficult to penetrate. Tumors that enter veins ultimately enter the vena cava and lodge in the lungs ([Fig. 6-23](#)) or enter the portal system and lodge in the liver. Neoplasms metastatic to the lungs may secondarily enter the arterial circulation. Some tumors have a notable predilection for veins. Pheochromocytomas of many species frequently enter the adrenal veins, where they may form large tumor masses extending into the vena cava.

6.6.3

### MECHANISMS OF INVASION AND METASTASIS

Metastasis is a complex process requiring invasion of the extracellular matrix (ECM), entry into blood vascular or lymphatic vessels, extravasation of tumor cells, and colonization of the metastatic site ([Fig. 6-24](#)). These activities require many coordinated alterations in cell-cell and cell-matrix adhesion, motility, and invasiveness. Due to the complexity of the metastatic process and the heterogeneity of tumor cells, metastasis is inefficient. Of the many tumor cells that enter the circulation, only a few are able to produce metastases. Local invasion is a prerequisite for metastasis; thus the two processes share many features.

268

269

Fig. 6-24 **The metastatic cascade.** This figure illustrates the sequential steps involved in the hematogenous spread of a tumor. Similar events occur during lymphatic spread. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

6.6.3.1

### ADHESION

As a first event in invasion and metastasis, tumor cells must detach from the main tumor mass, penetrate the basement membrane, and enter the ECM. For cells to separate from each other, intercellular adhesion structures, including desmosomes and adherens junctions, must be dismantled. In many tumor cells of epithelial origin, this occurs because of the loss of cadherin or catenin function. These molecules are essential structural elements of intercellular junctions. At the same time that tumor cells detach from each other, they must also establish contacts with ECM components. Integrins and other specific receptors on the tumor cell membrane recognize and bind to a variety of ECM components, such as fibronectin, laminin, collagen, and vitronectin. During invasion and metastasis, carcinoma cells often express increased numbers of these receptors. Moreover, instead of being localized to the basal surface of the tumor cell, the receptors are redistributed to cover the entire cell membrane. Tumor cells also appear to be able to modulate the types of ECM receptors that they express, allowing the cells to adapt to different microenvironments.

6.6.3.2

### INVASION

Nonneoplastic epithelial cells generally rest on a specialized extracellular structure called the basement membrane to which they are firmly attached by hemidesmosomes. In benign epithelial tumors the basement membrane usually remains intact, whereas in malignant tumors the neoplastic epithelial cells penetrate the basement membrane to invade surrounding tissue. Tumor cells actively degrade basement membrane and ECM components by increasing the net protease activity in their vicinity (Fig. 6-25). Net protease activity is determined by a variety of interacting factors, including the rate of protease synthesis, the rate at which proteases are activated, and the rate at which protease inhibitors are produced. Proteases and antiproteases may be produced and activated by the tumor cells themselves, or tumor cells may induce nonneoplastic stromal cells to produce these enzymes. Proteases that appear to play an important role in tumor metastasis include matrix metalloproteinases, such as type IV collagenase, and urokinase, a serine protease.

6.6.3.3

### MIGRATION

At many points during invasion and metastasis, tumor cells migrate actively. This migration appears to be mediated by coordinated alterations in the cytoskeleton and the cellular adhesion structures with which they are intimately associated. Tumor cell migration is stimulated by autocrine growth factors, such as hepatocyte growth factor, also called “scatter factor,” and by cleavage products of ECM components, including fragments of collagen.

269

270

**Fig. 6-25 Schematic illustration of the sequence of events in the invasion of epithelial basement membranes by tumor cells.** Tumor cells detach from each other because of reduced adhesiveness **(A)**. Cells then attach to the basement membrane via laminin receptors **(B)** and secrete proteolytic enzymes, including type IV collagenase and plasminogen activator. Degradation of the basement membrane **(C)** and tumor cell migration **(D)** follow. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.6.3.4 TUMOR EMBOLI

The processes by which tumor cells invade blood and lymphatic vessels, extravasate from these vessels, and invade the ECM at a metastatic site are variations on those discussed earlier. Once inside a lymphatic or blood vessel, tumor cells tend to associate to form small emboli. In vessels, tumor cells may be recognized and attacked by host lymphocytes or may be surrounded by platelets. Interestingly, platelets may actually protect the tumor embolus and enhance tumor metastasis. The site at which tumor cells exit the blood vascular or lymphatic system is determined both by the pattern of lymphatic or vascular drainage of the primary tumor and by the ability of tumor cells to interact with adhesion molecules on endothelial cells. In addition, metastatic sites must provide a suitable microenvironment for tumor cell growth. Some tumors preferentially metastasize to specific sites. For example, prostate carcinomas in both humans and dogs frequently spread to bone ([Fig. 6-26](#)).

### 6.6.4 METASTASIS SUPPRESSION

A wide variety of genetic and epigenetic changes affect tumor cell adhesion, motility, and protease production. Thus metastatic potential is probably the cumulative effect of many different genetic alterations, and it seems unlikely that any individual genetic change single-handedly makes a tumor metastatic. On the other hand, a small number of genes have been identified that seem to function to suppress metastasis effectively. A good example of a candidate metastasis suppressor gene is the gene encoding E-cadherin, a component of adherens junctions, because loss of intercellular junctions appears to be essential for tumor metastasis.

### 6.7 TUMOR STROMA

#### 6.7.1 COMPOSITION OF THE STROMA

A tumor consists of tumor cells proper, the tumor parenchyma, and nonneoplastic supporting structures, the stroma ([Fig. 6-27](#)). The stroma is composed largely of extracellular connective tissue and consists of proteins and glycoproteins, such as collagen, embedded in a complex matrix of proteoglycans. The stroma contains the blood vessels that supply nutrients to the tumor, fibroblasts, and a variety of inflammatory and immune cells. The amount of stroma associated with tumors can vary considerably. The extracellular material in the stroma of epithelial tumors is produced primarily by surrounding nonneoplastic mesenchymal cells, whereas many mesenchymal tumors can produce the ECM in their stroma. For instance, many osteosarcomas produce bone, a specialized form of connective tissue stroma. Stromal tissue may form a connective tissue capsule around epithelial tumors that limit neoplastic spread. In general, encapsulated epithelial tumors are considered to have a better prognosis than unencapsulated tumors ([Fig. 6-28](#)).

270

271

**Fig. 6-26 Prostate carcinoma, metastasis, femur, dog.** **A**, The gross photograph of a sectioned femur reveals metastatic prostate carcinoma (\*). **B**, The radiograph illustrates an osteolytic bone metastasis (Ca). In the regions between the arrows, extensive proliferation of new bone has occurred in response to the tumor. (**A** and **B**, Modified from Rosol TJ, Tannehill-Gregg SH, LeRoy BE et al: *Animal models of bone metastasis*. In Keller ET, Chung LWK, editors: *Cancer treatment and research*, Boston, 2004, Kluwer Academic Publishers.)

In the stroma of rare tumors, both mesenchymal and epithelial, there is an amorphous eosinophilic substance termed amyloid. Amyloid consists of one of a variety of abnormal proteins arranged in  $\beta$ -pleated fibrils. The proteins that form amyloid are usually secreted by the tumor cells themselves; for instance,  $\lambda$ -light chain protein secreted by neoplastic plasma cells forms the amyloid sometimes seen in the extramedullary plasmacytomas of various species.

Fig. 6-27 **Pancreatic adenocarcinoma, pancreas, dog.** The tumor parenchyma is divided into incomplete lobules by the tumor stroma (*arrows*) composed of collagen and extracellular matrix components in which blood vessels (*arrowheads*), fibroblasts, and inflammatory and immune cells are embedded. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

### 6.7.2 TUMOR-STROMAL INTERACTIONS

Tumor cells interact with their stroma in a complex fashion, exchanging a wide variety of signaling molecules, including growth factors, cytokines, hormones, and inflammatory mediators (Fig. 6-29). These exchanges modulate the growth rate, differentiation state, and behavior of both stromal and tumor cells. Platelet-derived growth factor released by tumor cells stimulates tumor-associated fibroblasts to increase the production of collagen. In some cases, this process leads to an extensive fibrous reaction, termed a scirrhous or desmoplastic response, in the stroma. Transforming growth factor- $\alpha$  of tumor origin can stimulate tumor-associated fibroblasts to differentiate into myofibroblasts, which are fibroblasts with contractile capabilities. Tumor-associated fibroblasts may acquire special characteristics that distinguish them from normal fibroblasts. Such fibroblasts may secrete a fetal type of ECM. In some tumors, tumor-associated fibroblasts acquire

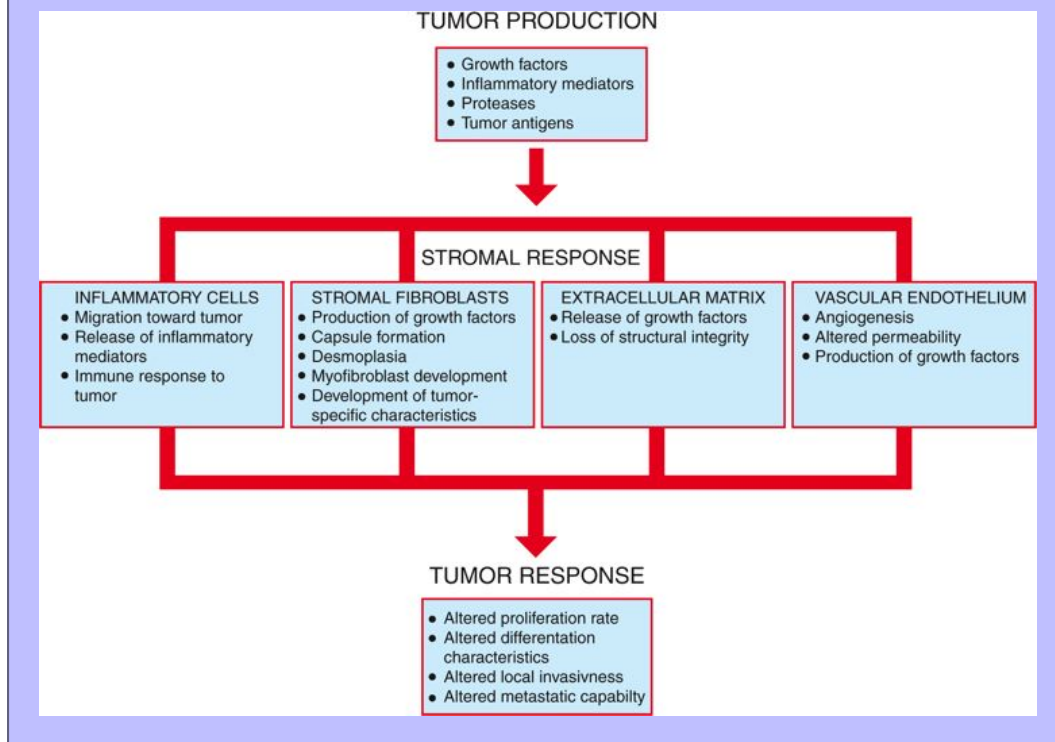

271

272

## Pathologic Basis of Veterinary Disease, 4th Edition

heritable genetic and epigenetic changes that allow them to co-evolve with adjacent tumor cells. Tumor cells may induce surrounding stromal cells to produce cytokines that promote tumor cell proliferation and motility. Furthermore, growth factors are sequestered in the ECM of the stroma, where they bind to proteoglycans. This interaction controls the bioavailability of these factors, which can be released from the ECM by the activity of proteases secreted by tumor cells, stromal fibroblasts, or inflammatory cells.

**Fig. 6-29 Tumor-stromal interactions.** Tumor cells and the stroma in which they are embedded interact in a variety of ways that serve to modify the growth and behavior of both elements. Tumor stroma may both enhance and limit tumor development and spread. (Redrawn with permission from Dr. D.F. Kusewitt, College of Veterinary Medicine, The Ohio State University.)

### 6.7.3 ANGIOGENESIS

Continued growth of solid tumors is absolutely dependent upon an adequate blood supply to provide oxygen and nutrients to tumor cells. Without the development of new blood vessels, a process termed angiogenesis, tumors are limited to a maximum diameter of 1 to 2 mm. At some point during tumor development, an angiogenic switch occurs that confers on tumor cells the ability to induce and sustain new tumor vasculature. Angiogenesis is a complex process involving recruitment of endothelial cells from preexisting blood vessels, endothelial cell proliferation, directed migration of endothelial cells through the ECM, and maturation and differentiation of the capillary sprout. Angiogenesis is controlled by the balance between a plethora of angiogenesis-stimulating and angiogenesis-inhibiting factors. Tumors induce angiogenesis by the production

272

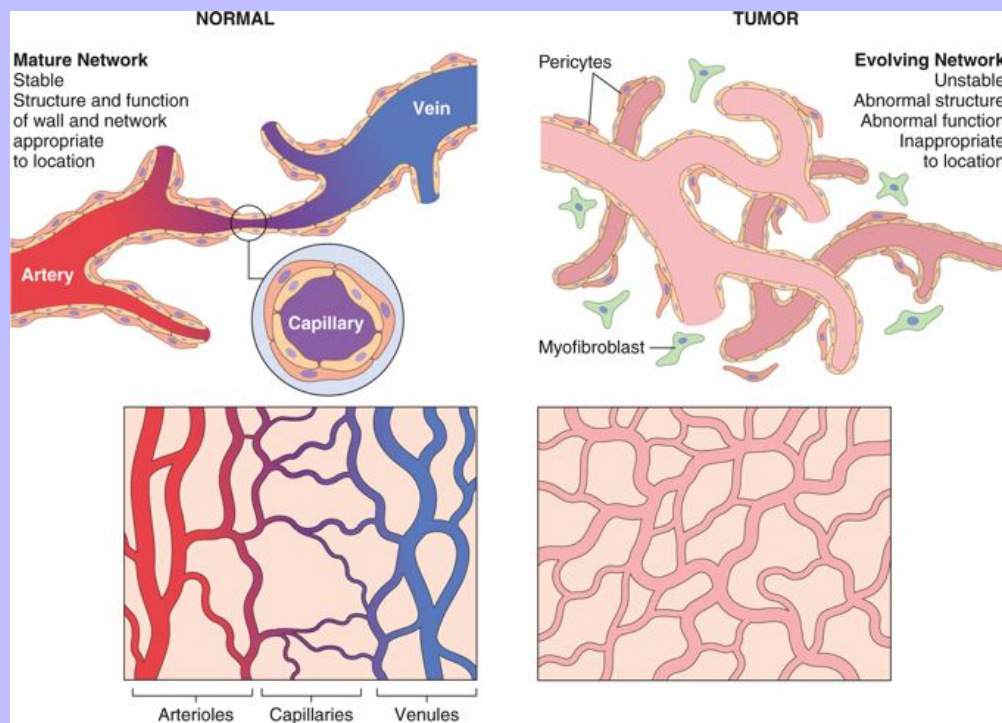

273

## Pathologic Basis of Veterinary Disease, 4th Edition

and release of angiogenic factors, such as vascular endothelial growth factor, or by down-regulating production of antiangiogenic factors, such as thrombospondin. In addition, angiogenic and antiangiogenic factors bound to ECM components can be released and activated by tumor protease activity. Vascular endothelial growth factor and acidic and basic fibroblast growth factors are among the most potent angiogenic factors produced by tumors. The tumor blood vessels that develop in response to angiogenic signals are usually more dilated, more tortuous, and more permeable than normal blood vessels (Fig. 6-30).

**Fig. 6-30 Tumor angiogenesis.** Compared with normal vessels (*left panels*), tumor vessels are tortuous and irregularly shaped (*right panels*). The tumor vasculature is formed from circulating endothelial precursor cells and existing host vessels; myofibroblasts give rise to pericytes that surround vessels. In contrast to the stable vessel network of normal tissue, the networks formed by tumor vessels are unstable and leaky. Arterioles, capillaries, and venules are clearly distinguishable in normal vasculature; in the tumor, vessels are disorganized and specific vessel types cannot be identified. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

In addition to supplying nutrients, tumor vasculature plays other roles in tumor development. Vessel leakiness allows perivascular deposition of a fibrin network that promotes formation of collagenous tumor stroma. The endothelial cells of tumor blood vessels produce growth factors, such as platelet-derived growth factor and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

interleukin (IL)-1, that can stimulate the growth of tumor cells. Moreover, without access to the circulatory system, tumors cannot metastasize. Because solid tumor growth is absolutely dependent on an adequate blood supply, therapeutic strategies to inhibit angiogenesis are being developed.

Investigation of the development of lymphatic vasculature of tumors has demonstrated that tumor	273
lymphangiogenesis shares many features with tumor angiogenesis. Tumor-associated lymphatic vessels sprout	274

from preexisting lymphatic vessels in response to tumor-secreted factors, such as vascular endothelial growth factor. Tumor-associated lymphatics appear to be essential for metastasis of solid tumors to regional lymph nodes. In human tumors, there is a strong correlation between the levels of vascular endothelial growth factor expression and lymphatic metastasis; and in genetically engineered mice that do not express vascular endothelial growth factor, lymphatic metastasis does not occur.

6.7.4

### INFLAMMATION

Many tumors are heavily infiltrated with neutrophils, eosinophils, mast cells, lymphocytes, histiocytes, or a combination of these cells. Inflammatory cells are attracted to tumors by chemokines and cytokines released by the tumor cells themselves or by mononuclear and polymorphonuclear cells infiltrating the tumor. Inflammatory cells serve as a source of prostaglandins, leukotrienes, and reactive oxygen species. In general, inflammation does not appear to protect against tumors. In fact, many chronic inflammatory conditions increase the risk of cancer in affected organs. As an example, the development of postvaccinal sarcomas in cats is clearly linked to the presence of inflammation at sites of inoculation. Moreover, in humans, epidemiologic studies suggest that nonsteroidal antiinflammatory drugs reduce the incidence of some cancers.

Fig. 6-31 **Tumor antigens recognized by CD8<sup>+</sup> T lymphocytes.** Note that all tumor antigens are presented to CD8<sup>+</sup> T lymphocytes by major histocompatibility (MHC) class I molecules. CTL, Cytotoxic T lymphocyte. (Modified from Abbas AK, Lichtman AH: *Cellular and molecular immunology*, ed 5, Philadelphia, 2003, Saunders.)

## 6.8 TUMOR IMMUNITY

### 6.8.1 TUMOR ANTIGENS

Tumor antigens are proteins, glycoproteins, glycolipids, or carbohydrates expressed on the tumor cell surface (Fig. 6-31). They include both tumor-specific antigens restricted to tumor cells and tumor-associated antigens present on both tumor cells and normal cells. Tumor antigens can be exploited both for diagnostic and

## Pathologic Basis of Veterinary Disease, 4th Edition

therapeutic purposes. Tumor antigens released into the blood stream allow noninvasive detection of tumors and monitoring tumor response to treatment. In combination with sophisticated imaging techniques, antibodies against tumor-restricted antigens can be used to localize tumors and detect metastases. Some tumor antigens can serve as the targets of effective immunosurveillance. However, many tumor antigens are not appropriate therapeutic targets. The antigens may not be restricted to tumor cells or may not elicit a strong cytotoxic response. Therapeutic strategies to enhance the immune response to tumor antigens are currently the subject of intense investigation.

Some tumor-specific antigens are newly expressed molecules, such as antigens derived from oncogenic viruses or altered cellular products encoded by mutated genes. In these instances, productive viral infection or gene mutation is restricted to tumor cells and their progeny. Embryonic antigens or oncofetal antigens, normally not expressed in adult tissue but reexpressed in tumor tissue, may also behave as tumor antigens. For instance, the developmental antigens, carcinoembryonic antigen and  $\alpha$ -fetoprotein, are reexpressed in some tumors in a variety of species and may be released into the circulation. Serology for these antigens is widely used to test for recurrence of liver and intestinal tumors in humans. Tumor-specific shared antigens are encoded by genes that have very limited expression in adult tissue but that are expressed by many types of tumor tissue. A striking example of useful tumor-specific shared antigens is the MAGE family of proteins, found in humans and other species. These antigens are not present on the surface of normal adult cells; however, they are expressed by a wide variety of tumor types and are promising candidates for antitumor immunotherapy. Tissue-specific antigens are shared by tumors and the normal tissues from which they arise. In some cases, these antigens are expressed only at specific stages of differentiation in the normal tissue and are thus termed differentiation antigens. When tissue-specific or differentiation antigens are expressed at considerably higher levels on tumor cells than normal cells, they may function much like tumor-specific antigens.

6.8.2

### IMMUNOSURVEILLANCE

It is likely that the vertebrate immune system evolved primarily for the purpose of recognizing and destroying infectious organisms and the host cells they infect. However, the immune system also attacks tissue transplanted from genetically dissimilar animals of the same or different species. In special instances, the immune system can respond to self-antigens. It has been postulated that the immune system is capable of recognizing self-antigens on tumor cells as foreign and attacking antigen-bearing tumor cells as if they were microbially infected cells or foreign cells. This process is termed immunosurveillance. It is argued that effective immunosurveillance suppresses tumor development and that a failure of immunosurveillance allows tumors to emerge. The immunosurveillance hypothesis is supported by the dramatically increased tumor susceptibility of immunosuppressed transplant recipients. The inability of these individuals to mount effective antitumor responses apparently allows the emergence of many tumors usually eliminated by immunosurveillance. The presence of lymphocyte and macrophage infiltrates within and around tumors of many types in many species also suggests that tumors can elicit an immune response. Finally, there is abundant experimental evidence that mice can mount an effective immune response against chemically induced tumors. Much of our knowledge of tumor immunity comes from experimental studies employing mice.

6.8.3

### ANTITUMOR EFFECTOR MECHANISMS

The body may mount a variety of immune responses against tumor antigens (Fig. 6-32). The type of immune response and its effectiveness against tumor cells is largely determined by the inherent immune responsiveness of the host and the characteristics of the tumor antigen under attack. The least specific immune response to tumor cells is carried out by the innate immune system. The innate immune response is believed to be the first line of defense against cancer cells. Antitumor effectors of the innate immune system, including NK cells and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

macrophages, do not require antigen-specific priming by dendritic cells. More specific immune responses are undertaken by the adaptive immune system, consisting of both cell-mediated and humoral components. The cell-mediated immune response is believed to mount the most effective antitumor defenses. Any adaptive antitumor immune response requires that tumor antigens be presented to immune cells in a recognizable context. Dendritic cells capture antigens that are secreted by viable tumor cells or released from dying tumor cells. The dendritic cells ingest these antigens, fragment them to a suitable size, link them to class I or class II major histocompatibility (MHC) antigens, and present them on the cell surface in association with appropriate co-stimulatory molecules. A dendritic cell can then interact with many different lymphocytes to prime their response to the specific tumor antigen presented by the dendritic cell. Antigen-activated CD8 and CD4 T lymphocytes develop into tumor-specific cytotoxic and helper T lymphocytes, respectively, whereas B lymphocytes develop into immunoglobulin-secreting plasma cells. CD8<sup>+</sup> lymphocytes recognize tumor antigens in the context of MHC class I antigens, whereas CD4<sup>+</sup> cells recognize these antigens only in association with MHC class II molecules.

6.8.3.1

### NATURAL KILLER CELLS

NK cells are lymphocytes that lack many of the usual markers of T or B lymphocytes. NK cells display a variety of receptors, both inhibitory and activating, that recognize MHC molecules and stress-induced ligands on tumor cells. NK cells can kill a wide variety of neoplastic and virally infected cells. Cells that express MHC class I molecules are preferentially spared by NK cells, whereas cells lacking MHC molecules are specifically targeted. After binding to a tumor cell, the NK cell releases lytic granules that activate apoptosis in the target cell. This mechanism of cell killing or cytolysis is shared with T lymphocytes and is discussed in more detail next.	275
	276

**Fig. 6-32 Cells involved in immunosurveillance against tumors.** Antitumor responses involve cytotoxic  $CD8^+$  and helper  $CD4^+$  lymphocytes, natural killer (NK) cells, macrophages, B lymphocytes, and a variety of immunomodulatory cytokines. CTL, Cytotoxic T lymphocyte;  $IFN-\gamma$ , interferon- $\gamma$ ;  $IgG$ , immunoglobulin G;  $IL-2$ , interleukin-2; MHC, major histocompatibility complex;  $TNF-\alpha$ , tumor necrosis factor- $\alpha$ . (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 6.8.3.2

#### MACROPHAGES

Macrophages are migratory phagocytic cells capable of killing tumor cells by releasing reactive oxygen intermediates, lysosomal enzymes, nitric oxide, and tumor necrosis factor. Their antitumor activity is stimulated by interferon (IFN)- $\gamma$ , which is produced by both T lymphocytes and NK cells. Macrophage-mediated tumor cell killing is independent of MHC antigens, tumor-specific antigens, and the type of transformed cell being targeted, but direct contact between the macrophage and tumor cell is required.

6.8.3.3

### T LYMPHOCYTES

Cytotoxic T lymphocytes (CTLs) are the primary effector cells of the adaptive antitumor immune response. Most CTLs are CD8<sup>+</sup> T lymphocytes that have been primed by dendritic cells to recognize and engage tumor antigens on the surface of tumor cells. When a CTL attaches to its target cell, a well-organized immunologic synapse is rapidly formed at the site of cell-to-cell contact and persists for more than an hour. Into this synapse, the CTL releases lytic granules containing perforin, a pore-forming protein, and granzymes, which are serine proteases. Perforin mediates the entry of granzymes into the target cell. Once inside the target cell, granzymes initiate both caspase-dependent and caspase-independent apoptosis. CD4<sup>+</sup> T lymphocytes do not appear to be essential for the generation or maintenance of a CTL response; instead, CD4<sup>+</sup> lymphocytes are generally considered to function as helper T lymphocytes that enhance the function of CD8<sup>+</sup> CTLs and antigen-producing B lymphocytes. CD4<sup>+</sup> T lymphocyte helper activities are largely mediated through secretion of cytokines such as IL-2, which drives CD8<sup>+</sup> cell proliferation, and IFN- $\gamma$ , which stimulates CD8<sup>+</sup> T-lymphocyte differentiation.

6.8.3.4

### B LYMPHOCYTES

Many tumor antigens can incite both cell-mediated and humoral immune responses. Antibody-producing B lymphocytes mediate the humoral immune response to tumors. Antibodies that recognize tumor antigens kill tumor cells by binding to the cells and activating a local complement cascade. Activation of the complement cascade generates a membrane attack complex that induces loss of tumor cell membrane integrity and rapid cell death with the morphologic hallmarks of necrosis. In addition, antitumor antibodies may be bound by their constant regions to NK cells or macrophages, leaving the variable regions of the immunoglobulins available for specific recognition of tumor antigens. This allows the effector cells to recognize, attach to, and kill tumor cells by the mechanism of antibody-dependent cell-mediated cytotoxicity (ADCC).

276

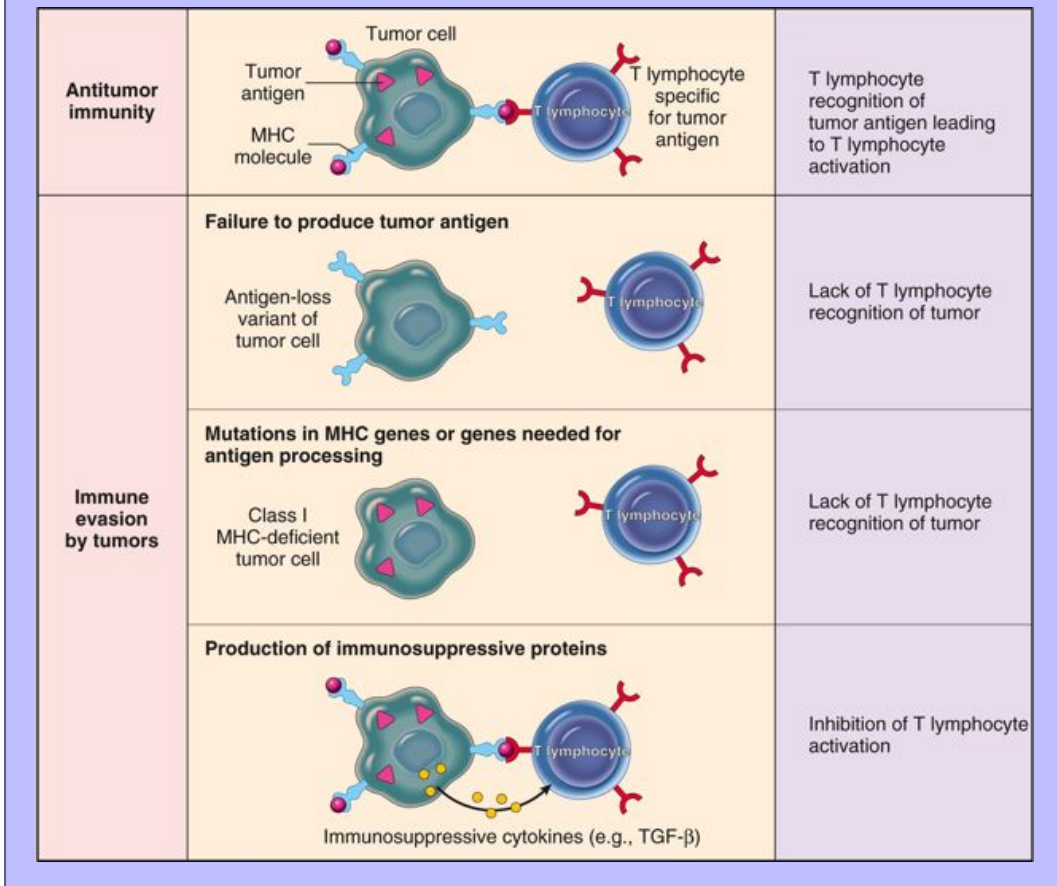

277

6.8.4

### EVASION OF THE IMMUNE RESPONSE

Many tumors are able successfully to evade immunosurveillance, using a variety of mechanisms ([Fig. 6-33](#)).

**Fig. 6-33 Mechanisms by which tumors evade the immune system.** Tumor cells employ a variety of mechanisms to avoid attack by cytolytic T lymphocytes. *MHC*, Major histocompatibility complex; *TGF-β*, transforming growth factor-β. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

6.8.4.1

### ALTERED MAJOR HISTOCOMPATIBILITY COMPLEX EXPRESSION

CTLs recognize tumor antigens only on tumor cells that display the antigens in the context of MHC class I molecules. Thus tumor cells that lose or down-regulate expression of class I MHC antigens may have a distinct selective advantage. However, tumors that fail to express class I antigens are more susceptible to NK cell killing. Tumors may also down-regulate expression of class II MHC antigens. Class II antigens are required for activation of the helper T lymphocytes that stimulate CTL differentiation, and loss of these antigens prevents the generation of an optimal antitumor CTL response.

### 6.8.4.2 ANTIGEN MASKING

Tumors may become invisible to the immune system by losing or masking tumor antigens. The outgrowth of clonal tumor variants that do not express tumor antigens will be favored during tumor evolution. Tumor antigens on the cell surface may be hidden from the immune system if they are complexed with glyocalyx molecules, fibrin, or even antibodies. Some humoral responses to tumor antigens may therefore promote tumor survival by protecting tumor antigens from recognition by CTLs.

277  
278

### 6.8.4.3 TOLERANCE

Although the immune system responds vigorously to non-self-antigens, it is tolerant to self-antigens. Thus tumor antigens shared with normal tissue usually are not able to evoke an immune response because the body has already been “tolerized” to the antigen. Tolerance can also result from presentation of non-self-antigens in a “tolerogenic” context (i.e., in the absence of co-stimulatory molecules required for effective T-lymphocyte activation).

### 6.8.4.4 IMMUNOSUPPRESSION

Tumor cells or their products may be immunosuppressive. Many tumors produce transforming growth factor- $\alpha$ , which inhibits the proliferation and function of lymphocytes and macrophages. Tumors may also produce Fas ligand. Fas ligand expressed by tumor cells binds to Fas receptors on nearby T lymphocytes and triggers their apoptosis. By this mechanism, T-lymphocyte clones that recognize a tumor may be specifically deleted. Finally, tumor cells release tumor antigens into the circulation that form immune complexes with antibodies, and these immune complexes may be immunosuppressive.

### 6.8.5 TUMOR IMMUNOTHERAPY

The fact that the antitumor immune response attacks only the tumor cells and not normal tissue makes it an attractive candidate as a therapeutic modality. Moreover, effective immunotherapy would reduce or eliminate the need to use highly cytotoxic chemotherapeutic agents that indiscriminately target dividing cells. These drugs can cause significant morbidity and mortality in cancer patients. To date, immunotherapy results have been variable and disappointing; however, many new approaches are presently under investigation, some of which show promise.

In general, immunotherapeutic strategies are aimed at (1) providing the patient with mature effector cells or antibodies that recognize and destroy tumors (passive immunotherapy) or (2) stimulating the immune response of the host against the tumor (active immunotherapy).

Administration of monoclonal antibodies raised against tumor antigens or tumor-specific effector lymphocytes generated in vitro generates rapid but short-lived passive tumor immunity. Monoclonal antibodies raised in other species have a limited usefulness because the tumor host may develop an immune response to these antibodies that abrogates their effectiveness. However, coupling toxins to monoclonal antibodies may allow targeted delivery of therapeutic agents to tumor cells. Antitumor lymphocytes are generated by removing lymphocytes from the host or tumor and expanding them in vitro by incubation with IL-2; these autologous immune cells are then readministered to the patient. Many approaches to stimulate the activity immunity of patients against their tumors have been attempted. These include vaccination with tumor cells or tumor antigens to generate antitumor CTLs, administration of cytokines to increase effector cell number and function, and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

nonspecific stimulation of the immune system by treatment with proinflammatory substances, such as bacterial products.

### 6.9 SYSTEMIC EFFECTS ON THE HOST

#### 6.9.1 DIRECT EFFECTS VERSUS PARANEOPLASTIC SYNDROMES

Tumors directly compromise the function of the organs in which they arise by replacing normal tissue and by disrupting normal anatomic relationships of affected organs. Both in the tissue of origin and in metastatic sites, expanding tumor tissue may compress surrounding normal tissue or the blood vessels that supply this tissue, resulting in pressure atrophy or frank necrosis. This is a particularly severe problem in organs encased in bone, such as the brain, that can expand to only a very limited extent. In the brain, even benign tumors that are not surgically accessible may prove fatal. Seizure activity is a common manifestation of brain tumors. Tumor invasion into the wall of a hollow organ such as the stomach may lead to organ rupture. Tumors may erode blood vessel walls, causing acute hemorrhage, whereas tumor extension into blood vessels may lead to the formation of tumor emboli that produce infarcts at distant sites.

In addition to direct effects, tumors may cause a variety of systemic clinical signs termed paraneoplastic syndromes. Paraneoplastic disorders are indirect and usually remote effects that are caused by tumor cell products rather than by the primary tumor or its metastases. Approximately 75% of human cancer patients develop paraneoplastic syndromes, but the incidence in veterinary cancer patients is not known. These syndromes are best described for the dog, although some affecting the cat and the horse have been reported (Table 6-3). Recognition of paraneoplastic syndromes is important for the following reasons: (1) Paraneoplastic syndromes may appear early in the course of tumor development and may be associated with specific tumor types, thus recognition of these syndromes can facilitate early tumor diagnosis; (2) treatment of the metabolic abnormalities associated with paraneoplastic syndromes and antitumor therapy may be required to assure effective cancer management; and (3) the severity of paraneoplastic abnormalities reflects the tumor burden; thus monitoring such abnormalities may be useful in determining tumor response to therapy and identifying tumor recurrence or spread.

### 6.9.2 CACHEXIA

Many animals with cancer show notable weight loss and debility. In cancer cachexia, both muscle and fat are lost, whereas in simple starvation fat is lost preferentially. Also, in starvation, there is a compensatory decrease in basal metabolic rate not seen in cancer cachexia. The etiology of cancer cachexia is complex. Contributing factors include anorexia, impaired digestion, nutritional demands of tumor tissue, nutrient loss in cancer-related effusions or exudates, and a variety of metabolic and endocrine derangements. Extra calories do not reverse the catabolic state of cancer cachexia. Many humoral factors, including cytokines and hormones, contribute to the development of cachexia. Among the best characterized of these factors are TNF- $\alpha$ , IL-1, IL-6, and prostaglandins.

### 6.9.3 ENDOCRINOPATHIES

A functioning neoplasm of an endocrine tissue produces the normal hormonal products of the tissue of origin, but the host is usually able to regulate this hormone production only to a very limited extent. Frequently, the result is an overproduction of hormone due to increased numbers of hormone-producing tumor cells, increased production of hormone by individual neoplastic cells, or both. In endocrine glands with more than one cell type, such as the pancreatic islet, the anterior pituitary, the thyroid, and the adrenal, generally only a single cell type becomes neoplastic. Thus a pancreatic islet cell adenoma will probably produce only a single hormone such as

## Pathologic Basis of Veterinary Disease, 4th Edition

insulin, glucagon, gastrin, or somatostatin, and not a combination of hormones. Several clinically significant endocrinopathies are seen fairly commonly in veterinary medicine. These include hyperthyroidism due to thyroid neoplasia in the cat, and Cushing's disease (hyperadrenocorticism) due to pituitary tumors in several species. A variety of nonendocrine neoplasms may also produce hormonally active substances not normally found in the tissue of tumor origin. This is termed ectopic hormone production. The hormone produced may be identical to the normally produced hormone, may be a modified form of the normal hormone, or may be the product of a gene that encodes a protein related to but not identical with the true hormone.

Probably the two most frequently observed metabolic derangements resulting from cancer-associated endocrine abnormalities in animals are hypercalcemia of malignancy and hypoglycemia. Hypercalcemia is seen with functional tumors of the parathyroid gland that produce excess parathyroid hormone, the major regulator of calcium levels in the body. In the great majority of cases, however, hypercalcemia of malignancy is due to ectopic production of parathyroid hormone and parathyroid hormone-related protein by neoplastic tissue, including a wide variety of carcinomas and sarcomas. In dogs, hypercalcemia is seen most frequently with adenocarcinoma of the anal sac (~90% of cases) (Fig. 6-34), lymphoma (~20% of cases), and multiple myeloma (~15% of cases). Hypercalcemia of malignancy in cats appears to be relatively rare. Parathyroid hormone and parathyroid-related hormone are encoded by two separate genes. The genes are regulated independently and produce proteins of somewhat different size and sequence. However, the amino terminal 34 amino acids of the two proteins are functionally equivalent. The hormones increase serum calcium by increasing calcium release from bones, enhancing reabsorption of calcium in the kidneys, and stimulating absorption of calcium in the intestine. Clinical signs of hypercalcemia include muscle weakness, cardiac arrhythmia, anorexia, vomiting, and renal failure. Hypercalcemia may also occur as a result of tumor metastasis to bone and resultant bone resorption; however, this is not a true paraneoplastic disorder because it is a direct effect of the tumor.

279

280

**Fig. 6-34 Apocrine gland carcinoma, anal sac, dog.** This tumor is composed of the typical solid lobules of malignant epithelial cells that characterize apocrine gland adenocarcinomas. Apocrine gland carcinoma, lymphoma, and multiple myeloma may be associated with hypercalcemia of malignancy. H&E stain. (Courtesy College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Hypoglycemia is seen primarily with insulinomas, functioning tumors of the pancreatic islet  $\beta$  cells. However, profound hypoglycemia of unknown origin may also occur with other tumor types. Due to the absolute dependence of the nervous system on glucose for energy, clinical signs of hypoglycemia are mostly neurologic and may include lethargy, incoordination, muscle weakness, and seizures.

6.9.4

### SKELETAL SYNDROMES

Hypertrophic osteopathy occurs in both cats and dogs. It usually presents clinically as a symmetric lameness. Radiographically, there is evidence of extensive periosteal new bone growth (Fig. 6-35). Hypertrophic osteopathy occurs with a variety of tumor types, although there is a strong association with space-occupying thoracic lesions, both neoplastic and nonneoplastic. The cause of this condition is not known, although abnormalities of growth hormone production are suspected. Myelofibrosis results from overgrowth of nonneoplastic fibroblasts in the bone marrow. It may be associated with myeloproliferative disease or with distant tumors. The cause is unknown.

**Fig. 6-35 Hypertrophic osteopathy, forelimbs, dog with a pulmonary tumor.** On this radiograph, the arrows indicate newly deposited bone that is less dense than normal cortical bone. Note that multiple bones on both limbs are affected and that new bone deposits are located primarily in the diaphyseal region of the long bones. (Courtesy Dr. J. Mattoon, College of Veterinary Medicine, The Ohio State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.9.5 VASCULAR AND HEMATOLOGIC SYNDROMES

Nonhematopoietic cancer in animals may result in a variety of vascular and hematologic syndromes, including eosinophilia and neutrophilic leukocytosis. The etiology of these conditions is unclear, but circulating cytokines are likely to be involved. Anemia is commonly seen in veterinary cancer patients. There are numerous potential causes for anemia in these animals, including anemia of chronic disease, bone marrow invasion, blood loss, and hemolysis. Polycythemia associated with ectopic production of erythropoietin has been reported. Thrombocytopenia is seen in approximately one third of all dogs with cancer. Disseminated intravascular coagulation (DIC) may be secondary to any large tumor. Anemia and DIC are frequently seen in dogs with hemangiosarcoma, a tumor that accounts for 7% of canine malignancies. Excessive immunoglobulin production by tumors, particularly monoclonal gammopathies due to multiple myeloma, can result in hyperviscosity syndrome, manifested as altered neurologic function, congestive heart failure, or bleeding disorders.

280

### 6.9.6 NEUROLOGIC SYNDROMES

Paraneoplastic neurologic disease in veterinary cancer patients is usually related to hypercalcemia, hypoglycemia, or hyperviscosity and is often manifested as seizure activity. Primary peripheral nervous system disease has also been reported. In many dogs with cancer, there is microscopic evidence of peripheral neuropathy; however, clinical signs of disease, such as areflexia, muscle weakness, reduced muscle tone, or paralysis, are much less common. Myasthenia gravis is occasionally seen in veterinary cancer patients, usually in association with a mediastinal tumor such as thymoma. The underlying defect in myasthenia gravis is a failure of nerve impulse transmission at neuromuscular junctions. Clinical signs include muscle weakness, reduced exercise tolerance, and dysphagia. Many neurologic paraneoplastic syndromes in humans are immune mediated, and this is likely to be the case in animals as well.

281

### 6.9.7 CUTANEOUS SYNDROMES

There are only a few reports of cutaneous manifestations of paraneoplastic disease in dogs and cats. Clinical signs of flushing, alopecia, or necrolytic dermatitis have been associated with a variety of tumor types. The syndrome of nodular dermatofibrosis in German shepherd dogs is a heritable disorder characterized by multiple benign-appearing fibrous nodules in the skin in conjunction with bilateral renal cystadenocarcinomas.

### 6.9.8 MISCELLANEOUS SYNDROMES

Gastrin-secreting tumors have been reported in dogs and cats. These tumors can cause gastroduodenal ulceration, abdominal pain, vomiting, and blood loss. Mast cell tumors are very common in dogs. Neoplastic mast cells produce a wide variety of biologic mediators, including histamine, heparin, platelet-activating factor, TNF- $\alpha$ , prostaglandins, and proteases. Release of these compounds, particularly histamine, is responsible for such paraneoplastic disorders as gastrointestinal ulceration and hemorrhage. Although widespread mastocytosis is frequently associated with clinical signs, cutaneous mast cell tumors rarely produce systemic signs.

### 6.10 GENETICS AND CANCER

Cancer is ultimately due to heritable changes in the DNA of the tumor cells. These changes are manifested in enhanced expression of normal proteins, decreased or absent expression of normal proteins, and expression of abnormal proteins. For instance, tumor suppressor proteins such as that encoded by p53 may fail to be expressed

## Pathologic Basis of Veterinary Disease, 4th Edition

---

or may be expressed in an inactive form. Oncogene-encoded proteins may be overexpressed or expressed in constitutively active form. The altered protein repertoire of the tumor cell determines its *phenotype*. Such changes create cells with the features of neoplasia, including unlimited proliferative potential, growth factor independence, resistance to apoptosis, and invasive capabilities.

Genetic alterations in the coding region of a gene clearly may result in the production of an altered protein as a result of an altered coding sequence or premature protein termination. However, changes in other regions of the genome may also affect the sequence of the encoded protein and the level at which it is expressed. An alteration in splice site sequence can yield incorrectly spliced mRNA that is translated into an aberrant protein. Because the 5' untranslated region of a gene generally contains its promoter and the 3' untranslated region often contains mRNA stabilization motifs, sequence alterations in these regions of the genome may also have profound effects on gene expression level.

### 6.10.1 STEPWISE ACCUMULATION OF CHANGES

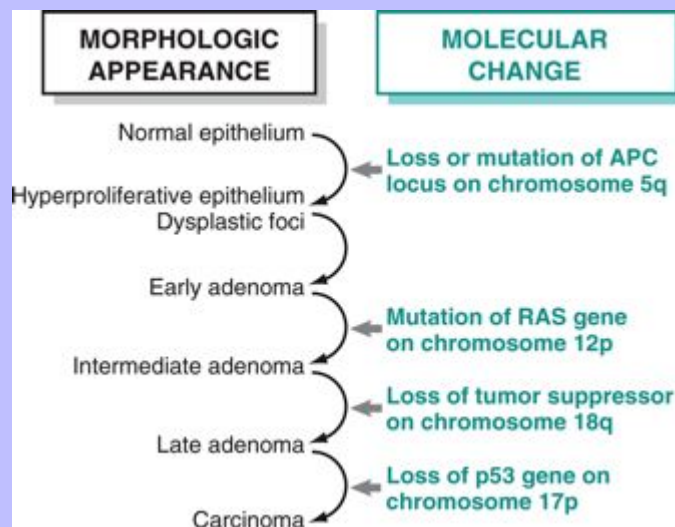

Cancer is associated with a progressive accumulation of genetic and epigenetic abnormalities. These defects lead to disruption of cell growth, cell death, apoptosis, differentiation, DNA repair, and other critical pathways. Some model systems demonstrate an orderly morphologic progression through premalignant to malignant to invasive and metastatic disease, and molecular genetic investigations of these various stages have made important contributions to our understanding of cancer biology. The molecular events that occur in the development of familial adenomatous polyposis, a form of human colorectal cancer, provide an excellent example of the genetic evolution that underlies progressive morphologic changes in cancer (Fig. 6-36). The initiating event is loss or mutation of the APC (adenomatous polyposis coli) tumor suppressor gene, leading to adenoma formation. This is followed by an activating mutation of a RAS oncogene and loss of genetic material harboring additional tumor suppressor genes. Ultimately a malignant carcinoma emerges.

As illustrated in Fig. 6-37, DNA is susceptible to many types of chemical and physical alterations. Some of these changes are due to injurious endogenous and exogenous agents. In addition, DNA alterations occur as part of normal processes of genome replication, repair, and rearrangement. Under some circumstances, these normal processes can lead to changes in DNA structure that contribute to the neoplastic phenotype. Furthermore, as tumors evolve, they often demonstrate reduced DNA repair capabilities and increased genomic instability. These developments accelerate the accumulation of genetic alterations in tumor cells.

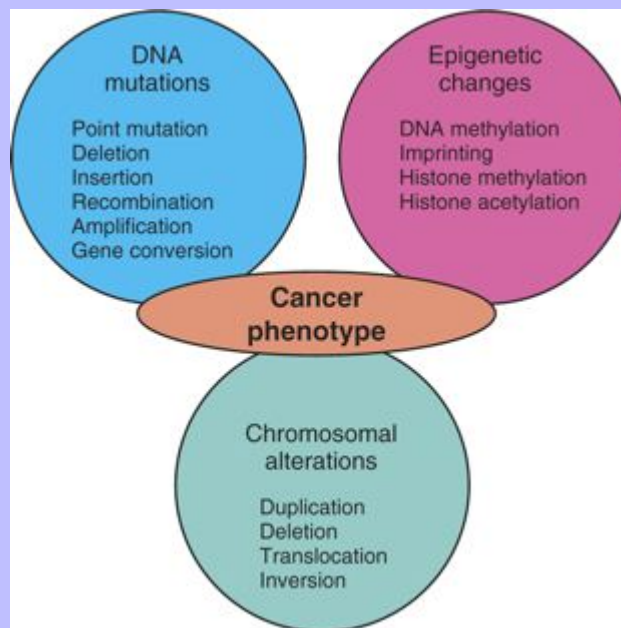

281

Fig. 6-36 **Molecular model for the evolution of human colorectal cancers through the adenoma-carcinoma sequence.** Although adenomatous polyposis coli (APC) mutation is an early event and loss of p53 occurs late in the process of tumorigenesis, the timing for the other changes may show variations. Note also that individual tumors may not have all of the changes listed. (Adapted from Vogelstein B, Kinzler KW: *Colorectal tumors*. In Vogelstein B, Kinzler KW, editors: *The genetic basis of human cancer*, New York, 2002, McGraw-Hill.)

**Fig. 6-37 Heritable alterations contributing to carcinogenesis.** Many genetic changes caused by extrinsic and intrinsic DNA-damaging agents, normal physiologic processes, and aging alter the amino acid sequences of encoded proteins and the levels at which these proteins are expressed. These changes in turn are responsible for the neoplastic phenotype. (Redrawn with permission from Dr. D.F. Kusewitt, College of Veterinary Medicine, The Ohio State University.)

Why do we study the molecular basis of cancer? Cancer is often treated using cytotoxic drugs and/or radiation therapy, neither of which discriminates between normal and tumor cells. Nonselective cell killing is responsible for many of the deleterious side effects of cancer treatment. More rational therapies would specifically target molecularly altered tumor cells, leaving nontumor cells lacking the molecular defect(s) relatively unharmed. Examples of molecularly targeted therapies used in humans include Gleevec, which is active against the BCR/ABL chromosomal translocation in chronic myeloid leukemia, and Iressa, which targets the epidermal growth factor receptor (EGF-R) in lung cancer. Specific molecular defects can also be exploited for early detection and/or early intervention at a stage when the tumor may be more responsive to treatment. Mutations in the BRCA1 gene are associated with a high risk for development of breast and/or ovarian cancer in women. Identification of the carrier status gives women the option of prophylactic mastectomy and/or oophorectomy. Mutations and other molecular defects can also be used to stratify patients for treatment and/or prognostic purposes.

### 6.10.2 GENETIC CHANGES IN CANCER

#### 6.10.2.1 DNA DAMAGE AND MUTATION

DNA damage, per se, does not constitute mutation. Mutation occurs during DNA replication, when the DNA strand containing unrepaired or misrepaired DNA damage is used as a template for the synthesis of a complementary DNA strand (see later discussion). At this time, unrepaired DNA lesions are misread by DNA polymerases, which insert incorrect bases in the newly synthesized DNA strand, and incorrectly repaired DNA lesions are reproduced in the daughter DNA strand. This process is known as mutation fixation; at least one and sometimes two rounds of replication are required for mutations to become fully fixed in the genome.

A chemical or physical change in an individual base may lead to the substitution of one base for another. The point mutation thus created can lead to altered protein sequence, if it is located in an exon or at a splice site, and to altered levels of expression, if it is located in the promoter or in the mRNA stabilization motif of a gene. Single- and double-strand breaks in DNA are caused by physical and chemical agents and viruses; they may also occur during normal physiologic processes, such as recombination of immunoglobulin genes and T-lymphocyte receptor genes. Although single-strand breaks are usually readily repaired, they can in some circumstances lead to gene conversion, the replacement of a gene or part of a gene by DNA derived from a closely related gene. Gene conversion is one mechanism by which organisms routinely generate diversity in large families of related genes, for example, major histocompatibility antigen genes. Double-strand breaks produce unprotected, recombinogenic DNA ends and often lead to major chromosomal anomalies, including deletions and translocations. Clearly, such large-scale chromosomal changes have the potential to alter the gene expression repertoire of a cell in a dramatic fashion. Insertions of DNA bases into the genome may be as small as a single base or larger than a viral genome. Insertion of individual bases by the enzyme terminal deoxynucleotide transferase is part of the system by which antibody diversity is normally generated. Retroviral genomes replicate only after insertion into the host genome, and these large insertions can interrupt the coding sequence of host genes, abrogating their expression. On the other hand, juxtaposition of viral promoter elements adjacent to cellular coding sequences can lead to dysregulated, often markedly increased, host gene expression. Unscheduled amplification of DNA segments is a poorly understood process by which multiple rounds of localized DNA replication produce hundreds or thousands of copies of DNA segments up to several megabases in length. Such amplified DNA segments may be visible in cytogenetic preparations as homogeneously staining regions in chromosomes or as episomal double minutes. Amplification of oncogenes or drug resistance genes may have significant effects on the life history of a tumor. Expansion or contraction of a small region of tandemly repeated DNA sequences can occur as the result of DNA polymerase slippage during replication. This process can introduce sequence alterations into protein encoding genes.

282

283

#### 6.10.2.2 CHROMOSOMAL INSTABILITY

The karyotypes of many tumor cells are extremely abnormal because of changes in chromosome number and configuration. These alterations are the result of chromosomal instability. In tumors with notable chromosomal instability, each cell in a tumor may have a different karyotype and exhibit a remarkable array of duplications, deletions, and reciprocal and nonreciprocal translocations. Such abnormalities can dramatically affect the levels of gene expression by altering the numbers of gene copies present and by juxtaposing regulatory and structural elements of unrelated genes. In some cases, specific chromosomal abnormalities are associated with specific disease entities. Probably the best studied example of such an

## Pathologic Basis of Veterinary Disease, 4th Edition

association is the relationship between chronic myeloid leukemia in humans and a reciprocal translocation between chromosomes 9 and 22 that yields an abnormal chromosome called the Philadelphia chromosome. This translocation fuses portions of the BCR and ABL genes; the fusion gene thus produced encodes an abnormal protein that appears to be responsible for neoplastic transformation of myeloid cells.

### 6.10.2.3 TYPES OF GENETIC ALTERATIONS IN CANCER CELLS

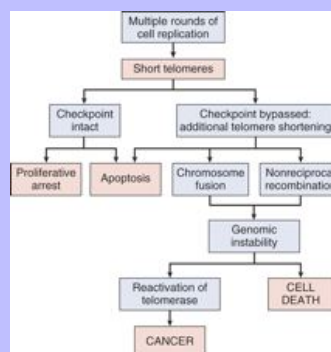

#### 6.10.2.3.1 Aneuploidy

The numerical aberrations in cancer can involve many different chromosomes or can be limited to a single chromosome. Cytogenetic analysis can determine the copy number of each chromosome. Monosomy is the term used when only one copy of a chromosome exists. Trisomy is the term used when three copies of a chromosome exist. For example, one quarter of canine lymphomas show trisomy of chromosome 13. In mice, trisomy of chromosome 15 occurs in almost all T-lymphocyte lymphomas and leukemias, suggesting that overexpression of a gene or genes on this chromosome plays an important role in tumor causation. Alterations in chromosome number (aneuploidy) are largely the result of mistakes in chromosome segregation due to multipolar spindles, centrosome amplification, kinetochore malfunction, or abnormal cytokinesis.

#### 6.10.2.3.2 Translocation

Translocations often occur when the cell response to DNA damage is dysregulated. When cells respond appropriately to DNA damage, multiple signaling cascades, such as the p53 pathway, are activated, leading to cell-cycle arrest, enhanced DNA repair, and, in the face of excessive DNA damage, apoptosis. However, if these pathways are no longer functional, chromosomal instability results. Dysfunctional telomeres also contribute to chromosomal instability (Fig. 6-38). The precise mechanisms by which an intact DNA damage response and normal telomerase activity maintain chromosomal integrity are not known.

**Fig. 6-38 Cellular responses to telomere shortening.** The figure shows the response of cells with intact cell-cycle checkpoints and of cells with checkpoint defects. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

283

### 6.10.2.3.3 Mutation

In addition to abnormal numbers of chromosomes, mutations (heritable change in the DNA sequence) are also present in most tumors. Mutations can result in a lack of or inactivation of a protein. On the other hand, some mutations cause uncontrolled activation of a protein. One example is a point mutation of the RAS oncogene. This mutation causes constitutive and unregulated activation of the protein and gives the affected cell a growth advantage over surrounding normal cells. Another type of mutation is a dominant-negative mutation, in which the mutant gene product causes inactivation of the wild-type product, effectively eliminating the cellular contribution of the normal gene. A missense mutation that changes a codon for one amino acid into a codon for a different amino acid has been identified in the Birt-Hogg-Dubé (BDH) gene in German shepherd dogs with hereditary multifocal renal cystadenocarcinoma and nodular dermatofibrosis (see later discussion).

### 6.10.2.3.4 Deletion

Deletions involve loss of DNA from a chromosome and can be as small as one base pair or as large as an entire arm of a chromosome. Heterozygous deletions occur on only one chromosome, whereas homozygous deletions occur on both chromosomes. Small deletions of one or two base pair cause a shift in the reading frame during protein synthesis (frameshift mutation). One possible consequence is that the mutated sequence codes for a premature stop codon, resulting in a truncated protein. Large deletions often encompass chromosome regions that harbor tumor suppressor genes.

### 6.10.2.3.5 Amplification

Genomic amplifications result in the presence of more than one diploid copy of a DNA sequence. The amplified region can involve large segments of a chromosome and encompass millions of base pairs. Alternatively the amplified region may be very small and contained within a portion of a single gene, such as the internal tandem duplication (ITD) of the c-kit gene in canine mast cell tumors. Regions of genomic amplification are useful for identifying potential oncogenes.

## 6.10.2.4 EPIGENETIC MECHANISMS OF ALTERED GENE EXPRESSION

### 6.10.2.4.1 Definition of “Epigenetic”

Epigenetic alterations have recently come to light as being major players in tumor biology. The term *epigenetic* refers to a heritable change in gene expression in somatic cells resulting from something other than a change in the DNA sequence. The most frequently studied epigenetic changes are DNA cytosine methylation and histone modifications. These epigenetic modifications can enhance or suppress gene expression and can be transmitted to daughter cells during cell division. Although DNA methylation and histone modifications are carried out by normal cellular enzymes, the activity and specificity of these enzymes can be altered by exogenous agents acting through a variety of oncogenic pathways. And although epigenetic changes are stable for the most part, they can be modulated with various pharmacologic agents. This quality makes them attractive targets for therapeutic intervention designed to restore gene expression to its normal state.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.10.2.4.2 Types of Epigenetic Changes in Cancer Cells

#### 6.10.2.4.2.1 DNA methylation

DNA methylation involves the addition of a methyl group to the No. 5 carbon of cytosine, in cytosines located immediately 5' to guanine (CpG dinucleotide). The methylation process is carried out by various methyltransferase enzymes. Methylation is essential for regulating gene expression in normal cells. Cancer cells, however, are characterized by an overall decrease in 5-methylcytosine in the bulk of the genome (global hypomethylation) with a paradoxical increase in gene-specific methylation of clusters of CpG sites located in the promoter and/or exon 1 of genes (CpG islands). In general, hypomethylation of genes, particularly of promoter regions, leads to gene activation, whereas hypermethylation results in gene silencing. Promoter methylation has been found in every type of human cancer studied (Fig. 6-39).

#### 6.10.2.4.2.2 Imprinting

Another situation in which methylation plays a role is in imprinting. Genomic imprinting refers to the parent-of-origin, allele-specific expression of certain genes whereby only the maternal or paternal allele is expressed. This monoallelic expression is controlled in part by DNA methylation, but this regulation is sometimes lost in cancer. The loss of imprinting can allow a double dose of a growth-promoting gene product. For example, insulin-like growth factor-2 (IGF-2) is an imprinted gene that is expressed from only the paternal allele in most normal tissue. If a cancer cell undergoes relaxation of imprinting, the methylation-mediated silencing of one allele is lost, enabling biallelic expression and higher than normal levels of this growth-promoting gene product.

#### 6.10.2.4.2.3 Histone modification

In addition to DNA methylation, a second type of epigenetic regulation involves histone modification. DNA is wound around histones to form chromatin. Chromatin can exist in an open configuration in which DNA is accessible to transcription factors (euchromatin) or in a closed, compact configuration in which DNA is inaccessible to transcription factors (heterochromatin). Posttranslational modifications, such as acetylation, methylation, and phosphorylation, take place on the histone tails. In the aggregate, these modifications form the “histone code,” which plays an important role in determining gene expression. For example, the addition of a negatively charged acetyl group ( $\text{CH}_3\text{CO}^-$ ) to certain lysine residues in a histone tail results in a weaker bond between the DNA and the histone. This allows a relaxed chromatin configuration and increases transcription of the associated gene. (Fig. 6-40).

**Fig. 6-39 CpG island methylation.** In most normal tissues, the dense clusters of CpG sites in the 5' regions of genes (CpG islands) are unmethylated (*open lollipops*), whereas those in the body of the gene are methylated (*filled lollipops*). The reverse is often seen in cancer where 5' CpG islands become hypermethylated, and there is concurrent hypomethylation of CpG sites in the body of the gene. Unmethylated 5' CpG islands are associated with active transcription (*arrow*), whereas methylated 5' CpG islands are associated with transcriptional repression (*x*). (Redrawn with permission from Dr. L.J. Rush, College of Veterinary Medicine, The Ohio State University.)

### 6.11 CANCER ETIOLOGY

The genetic alterations that contribute to cancer development include both heritable changes in germline sequences present in all cells within an organism, and somatic changes that accumulate in individual cells and tissues of the body over time. Human families and genetically related animals that exhibit distinct mendelian inheritance of specific types of cancer are said to have cancer syndromes. In these cases, a single germline mutation is generally responsible for tumor development. In contrast, sporadic tumors occur randomly in the population and are not associated with specific germline characteristics.

#### 6.11.1 GERMLINE MUTATIONS AND CANCER SYNDROMES

Heritable genetic lesions undergo germline transmission from one generation to the next, and the affected individual is born with one defective copy of a gene in each cell. Heritable mutations may be linked to familial cancer syndromes. Characteristics of heritable familial cancers include an early age of onset compared with sporadic cases, the formation of bilateral tumors in paired organs, the occurrence of multiple primary tumors in nonpaired organs, and a family history of cancer. Although many of the familial cancer syndromes are due to mutations in recessive tumor suppressor genes, the syndromes generally show a predominantly autosomal dominant pattern of inheritance. This apparent paradox is explained later in the discussion of hereditary retinoblastoma. Some cancer syndromes show a recessive mode of inheritance. In such syndromes, the affected individual must inherit the genetic defect from both parents. For instance, the mutant *ter* gene carried by strain 129/Sv-ter mice confers high susceptibility to testicular teratoma when present in the homozygous state, but not when carried in the heterozygous condition. Interestingly, the role of germline mutations in oncogenes in hereditary cancer syndromes remains unclear.

285

286

**Fig. 6-40 Histone acetylation.** DNA is wound around histones. The presence of acetyl groups (Ac) on histone tails is associated with relaxed chromatin, which is permissive to gene transcription. Removal of acetyl groups by histone deacetylases results in a closed chromatin configuration that is less permissive to the transcription machinery. (Redrawn with permission from Dr. L.J. Rush, College of Veterinary Medicine, The Ohio State University.)

The seminal work that identified the retinoblastoma (RB) tumor suppressor gene came about through the study of such inherited cancer syndromes (see later discussion). Other well-known inherited cancer syndromes in humans include germline mutations of p53 in Li-Fraumeni syndrome, mutations of NF1 and NF2 that lead to neurofibromatosis, mutations of BRCA1 and BRCA2 associated with breast and ovarian cancers, and mutations in MEN1 and RET, which are associated with multiple endocrine neoplasia. A well-documented veterinary cancer syndrome is the disease with the unwieldy name “hereditary multifocal renal cystadenocarcinoma and nodular dermatofibrosis” that occurs in the German shepherd dog. This disease is characterized by bilateral and multifocal renal tumors, uterine leiomyomas, and nodules in the skin (dermatofibrosis). The gene responsible has been mapped to a locus homologous to the human Birt-Hogg-Dubé locus, mutations which cause a phenotypically similar human disease.

Although the inherited cancer syndromes account for less than 10% of all human cancers, they have led to the identification of a number of important tumor suppressor genes that also play a significant role in sporadic tumors. In dominant cancer syndromes, tumor risk is very markedly increased because of changes in a single gene; however, there are also a variety of tumor susceptibility genes that alter cancer incidence to a considerably lesser extent. A variety of cancer susceptibility patterns have been identified in the dog as shown in [Table 6-4](#). The tumor susceptibility genes identified to date generally encode proteins involved in carcinogen metabolism or DNA repair. Their effects are substantially modified by interactions with each other and with the environment. For instance, the lack of pigmentation in white cats contributes to their susceptibility to squamous cell carcinoma of the ears; however, sun exposure makes a major contribution to tumor incidence in these animals.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 6-4 Cancer Susceptibility in Dogs

Tumor Site	Tumor Type	Susceptible Breeds	Resistant Breeds
Hematopoietic system	Lymphoma	Boxer	Crossbreeds
	Malignant histiocytosis	Bernese mountain dog	
Brain	Various	Boston terrier, boxer, bulldog	
Skin	Mast cell tumor	Boxer, bulldog, retriever	
	Vascular tumor		
	Hemangiosarcoma	German shepherd	
Mammary gland	Various	Boxer, * Brittany spaniel, dachshund, English setter, Labrador retriever, pointer, Springer spaniel	Boxer, * German shepherd, crossbreeds
Nose and sinuses	Various	Airedale, collie, Scottish terrier	
Oropharynx	Various	Boxer, cocker spaniel, golden retriever	Beagle, dachshund
Ovary	Carcinoma	Pointer	
Pancreas	Carcinoma, insulinoma	Airedale terrier, poodle	
Thyroid	Carcinoma	Beagle, boxer, retriever	Poodle
Skeleton	Osteosarcoma	Giant breeds, boxer, Danish dog, German shepherd, rottweiler	Crossbreeds
Testis		Boxer, collie, German shepherd	
Urinary bladder	Carcinoma	Beagle, collie, Scottish terrier

\* Information obtained from two independent studies.

### 6.11.2 ACQUIRED SOMATIC MUTATIONS

In contrast to germline mutations, acquired mutations occur in somatic cells and are restricted to individual cells and their progeny. These mutations are not passed through the germline. Whatever the germline genetic background upon which a tumor develops, additional genetic changes are required in the specific cells that give rise to the tumor. Somatic genetic alterations are caused both by intrinsic and extrinsic agents. These changes accumulate randomly over time, thus aging dramatically increases the risk of cancer. The graph shown in [Fig. 6-41](#) illustrates the increased risk of cancer with age in the human population, for which solid epidemiologic data are available. Somatic mutations are responsible for the majority of cancers in humans and probably in animals.

286

287

**Fig. 6-41 Cancer incidence by age in the human population of the United States for the year 2001.** Cancer incidence is shown as the number of cases of invasive cancer per 100,000 persons. Data for all races and all cancer sites are combined. Basal and squamous cell carcinomas of sun-exposed skin and all in situ cancers except urinary bladder cancers are excluded. Data are from selected state and metropolitan area cancer registries and cover approximately 92% of the U.S. population. (Compiled by Dr. D.F. Kusewitt from data released by the Centers for Disease Control and Prevention.)

### 6.11.2.1 INTRINSIC FACTORS

As a byproduct of ordinary metabolism, a variety of DNA damaging agents are produced, including reactive oxygen species. Moreover, DNA is susceptible to ordinary hydrolytic attack. These processes induce a variety of DNA lesions that can result in mutation. Moreover, in the course of many rounds of replication, DNA changes are introduced as a result of DNA polymerase errors. Illegitimate recombination, inappropriate nucleotide addition, and altered DNA methylation, activities carried out by normal cellular enzymes, can lead to the accumulation of DNA alterations. Chromosomal abnormalities also arise as a result of decreased telomere length, altered telomerase activity, and mistakes in chromosome segregation.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.11.2.2 EXTRINSIC FACTORS

Extrinsic factors that interact with DNA to cause cancer include chemical, physical, and infectious agents. Mutagens are agents that create DNA damage that gives rise to mutations, whereas carcinogens are agents that cause cancer. Many mutagens are also carcinogens. However, there are carcinogens with unknown mechanisms of action; such carcinogens may or may not be mutagens.

#### 6.11.2.2.1 Chemicals

Chemical carcinogens are widespread in the environment. All animals are exposed to low levels of carcinogens in air, water, food, and medications; accidental exposure to very high levels of carcinogens occasionally occurs. One notable chemical cause of cancer in animals is the bracken fern plant, the toxin of which causes urinary bladder cancer in cattle grazing pastures containing the plant. Unlike humans, however, animals do not voluntarily expose themselves to potent carcinogens, such as tobacco smoke.

#### 6.11.2.2.2 Radiation

Natural sources of radiation include the sunlight and cosmic rays that bombard the earth and naturally occurring radioisotopes, such as radon, in the soil. Medical procedures, including diagnostic radiographs and radiation therapy, can provide substantial radiation exposure. Radiant energy with wavelengths greater than  $5 \times 10^{-5}$  cm (visible light, infrared radiation, microwaves, radio waves, and electrical waves) is generally considered to be noncarcinogenic. However, shorter wavelength  $\gamma$ -rays, x-rays, and ultraviolet radiation can cause notable DNA damage and resultant mutation. In addition, high-energy particles, including  $\alpha$ -particles (helium nuclei),  $\beta$ -particles (electrons), and neutrons, can be carcinogenic. Ionizing radiation includes those forms of radiation with enough energy to eject electrons from target molecules ( $\gamma$ -rays, x-rays,  $\alpha$ -particles,  $\beta$ -particles, and neutrons). Because most animals have hair, ultraviolet radiation is generally not an important veterinary carcinogen. There are, however, two instances in which the ultraviolet radiation in sunlight poses a significant risk to animals: squamous cell carcinoma of the ears in white cats and ocular squamous cell carcinoma in Hereford cattle with nonpigmented eyelids.

287

288

#### 6.11.2.2.3 Infectious Agents

Viruses as a cause of cancer were first identified and have been most thoroughly studied in animals. Virally induced tumors in animals often affect a relatively large number of animals in a flock or herd, frequently arise in relatively young animals, and generally show a pattern of occurrence consistent with an infectious cause. There are many types of oncogenic viruses that induce cancer by a large variety of mechanisms. Table 6-5 summarizes those viruses of significance to veterinary medicine. Oncogenic retroviruses are small RNA viruses that cause many neoplastic diseases of importance in animals, including avian leukosis, feline leukemia, and bovine leukosis. Oncogenic DNA viruses include papillomaviruses that cause skin cancer, hepadnaviruses associated with liver cancer, and herpesviruses that induce adenocarcinomas, lymphomas, and leukemias. Species of *Helicobacter* bacteria have been recently demonstrated to play a role in gastric carcinoma and gastric lymphoma in ferrets and mice and in hepatocellular carcinoma in mice.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 6-5 Oncogenic Viruses of Animals

Classification	Virus	Species Affected	Associated Tumors
Retrovirus	Mouse mammary tumor virus	Mouse	Mammary adenocarcinomas
	Avian sarcoma-leukosis virus complex	Fowl	Various sarcomas, carcinomas, lymphomas, leukemias
	Avian reticuloendotheliosis virus complex	Fowl	Lymphomas, leukemias
	Mouse leukemia and sarcoma viruses	Mouse	Various sarcomas, carcinomas, lymphomas, leukemias
	Feline leukemia virus	Cat	Leukemias, lymphomas
	Bovine leukosis virus	Cattle	Leukemias, lymphomas
	Primate leukemia and sarcoma viruses	Primate	Fibrosarcomas, leukemias
	Mason-Pfizer monkey virus	Primate	Fibrosarcomas
	Feline immunodeficiency viruses	Cat	Lymphomas
	Maedi-Visna virus	Sheep	Pulmonary carcinomas
Hepadnavirus	Hepatitis B group	Primate, rodent, duck	Hepatocellular carcinomas
Papovavirus	Polyoma	Mouse	Various carcinomas, sarcomas
	SV40	Primate	Sarcomas (in rodents)
Adenovirus	Papilloma	Many species	Papillomas, carcinomas
	Types 2, 5, 12	Human	Sarcomas (in hamsters)
Herpesvirus	Frog herpesvirus	Frog	Adenocarcinomas
	Marek's disease	Fowl	Lymphoproliferative disease
	<i>Herpesvirus ateles</i> <i>Herpesvirus saimiri</i>	Primate	Lymphomas, leukemias
Poxvirus	Various	Various	Fibromas, papillomas

### 6.11.3 MECHANISMS OF CARCINOGENESIS

#### 6.11.3.1 CHEMICAL

A very wide variety of chemicals can cause cancer. Direct-acting chemical carcinogens are effective in the form in which they enter the body, but most carcinogens are procarcinogens that require metabolic activation by cellular enzymes to form ultimate carcinogens. These are thus termed indirect-acting carcinogens. Despite their varied composition, the effective form of most carcinogens is an electrophilic compound that binds covalently to DNA to form DNA adducts. [Fig. 6-42](#) illustrates the general mechanism of chemical carcinogenesis.

As discussed previously, experimental carcinogenesis studies have been critical in elucidating the stepwise development of cancer. Moreover, these studies have clearly defined the contribution of initiating versus promoting agents to cancer development ([Fig. 6-43](#)). In multistage tumorigenesis models, such as the skin carcinogenesis model in mice, the initiator must be administered before the promoting agent. The initiator is

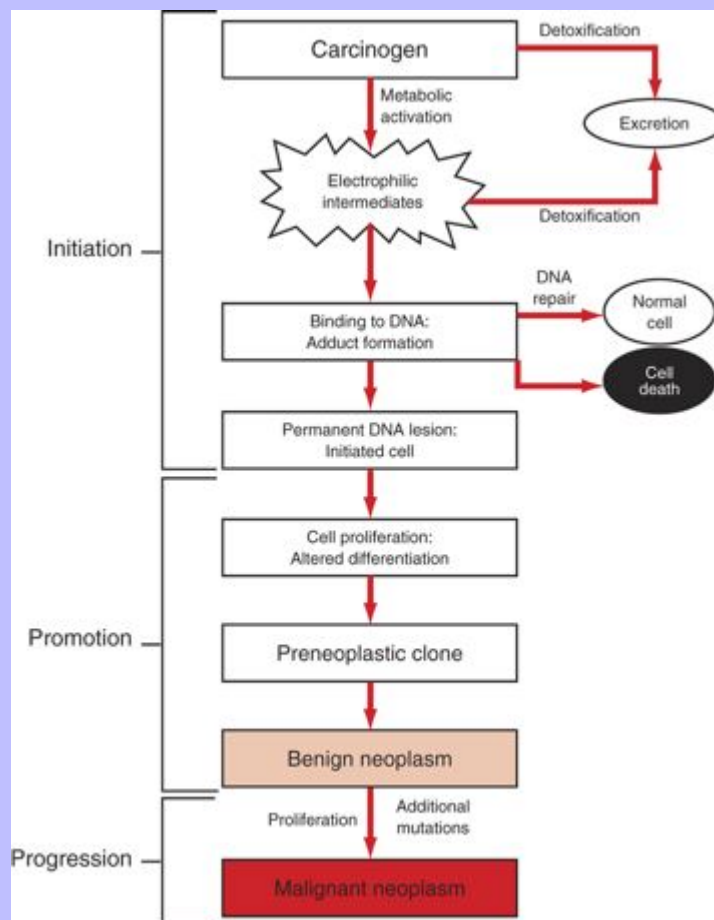

288

289

## Pathologic Basis of Veterinary Disease, 4th Edition

ineffective without subsequent application of a promoter. Moreover, multiple closely spaced promoter treatments are required to drive tumor emergence.

**Fig. 6-42 General schema of events in chemical carcinogenesis.** Note that promoters cause clonal expansion of the initiated cell, thus producing a preneoplastic clone. Further proliferation induced by the promoter leads to formation of a benign neoplasm. Accumulation of additional mutations during the phase of tumor progression results in emergence of a malignant tumor. (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 6.11.3.2 RADIATION

Unlike chemicals, all forms of radiation are complete carcinogens (i.e., they are able both to initiate and, with continued exposure, to promote tumorigenesis). Direct DNA damage due to ionizing radiation consists

## Pathologic Basis of Veterinary Disease, 4th Edition

primarily of single- and double-strand breaks and base elimination. However, ionizing radiation also generates free radicals from many cellular molecules. The interactions of these highly reactive molecules result in many forms of indirect DNA damage, including altered bases and DNA-protein cross-links. Absorption of ultraviolet radiation by DNA results in the formation of hallmark DNA adducts, pyrimidine dimers, which are potentially mutagenic. To a lesser extent, ultraviolet radiation generates reactive oxygen species, leading to indirect DNA damage like strand breaks and DNA-protein cross-links.

**Fig. 6-43 Experiments demonstrating the initiation and promotion phases of chemical skin carcinogenesis in mice.** Tumors arose only if application of an initiator was followed by multiple applications of a promoter. For group 2, application of the promoter was repeated at twice-weekly intervals for several months. For group 3, application of the promoter was delayed for several months and the promoter was then applied twice weekly. When the promoter was applied at monthly rather than twice-weekly intervals (group 6), it did not effectively promote tumor emergence. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 6.11.3.3 VIRAL

Although a common feature of most oncogenic viruses is the requirement for a DNA stage during viral replication, they employ a remarkable array of direct and indirect mechanisms to induce cancer.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.11.3.3.1 Dominant Oncogene

The genomes of many rapidly transforming viruses include a dominant oncogene that drives tumor development. Oncogenes may be of ancient or more recent host cell origin, such as the *fes*, *fgr*, *abl*, *fms*, and *kit* genes transduced by oncogenic retroviruses of cats. Viruses may also contain oncogenes not of host cell origin. For example, papillomavirus genomes include the E6 and E7 genes that encode inhibitors of the p53 and pRb tumor suppressor proteins, respectively; some viruses contain genes that encode growth stimulatory molecules, such as the small T antigen of SV40.

### 6.11.3.3.2 Insertional Mutagenesis

Viruses that do not possess their own oncogenes can instead activate expression of cellular oncogenes by a process of insertional mutagenesis. For example, most tumors caused by the avian leukosis virus exhibit a similar site of viral insertion, suggesting that virally induced alterations in genes at that site in the host genome are essential for tumorigenesis.

289

290

### 6.11.3.3.3 Hit and Run Mechanism

In the two mechanisms discussed previously, the viral genome or portions of the genome persist in the host cell. However, some viruses also cause tumors merely by transient residence in target cells. The precise mechanism by which this might occur has not been elucidated. Bovine papillomavirus uses such a *hit and run* mechanism of cell transformation.

### 6.11.3.3.4 Indirect Mechanisms

Viruses may also stimulate tumorigenesis by suppression of the host immune system or stimulation of target cell proliferation. The herpesvirus that causes Marek's disease is an example of a virus that suppresses the ability of the host to eliminate transformed cells, whereas hepatitis viruses exemplify viruses that stimulate cell proliferation.

## 6.12 MOLECULAR DETERMINANTS OF CANCER

### 6.12.1 TUMOR SUPPRESSOR GENES

Cells receive signals for both growth stimulation and inhibition, and must maintain the proper balance between these stimuli. The designation of tumor suppressor gene was originally given to genes that inhibited cell growth. Over time, the class of tumor suppressor genes has expanded to include many different types of cancer-related genes that, when inactivated through genetic and/or epigenetic means, lead to uncontrolled proliferation or tumor growth. This includes genes that control cell cycle, apoptosis, DNA repair, and other fundamental pathways.

The pivotal concept of tumor suppressor genes was posited by Alfred Knudson in 1971, based on his observations of children with familial and sporadic retinoblastoma, an uncommon tumor arising in retinoblasts. Knudson's two-hit hypothesis states that both alleles of a tumor suppressor gene must undergo mutation (i.e., a genetic "hit") for cancer to develop. In inherited cancer syndromes, the person is born with a mutation in one allele of all cells in the body (Fig. 6-44). The second hit is acquired as a somatic mutation of the tumor

## Pathologic Basis of Veterinary Disease, 4th Edition

---

suppressor gene in one cell and leads to cancer development at a much earlier age than in a person who was not born with the germline mutation. The development of a sporadic tumor requires that a person sustain two hits, one on each allele of the same gene in the same cell, which has a much lower probability of occurrence.

Loss of both alleles in a single cell is a rare event; however, loss of only one allele occurs much more frequently. If this takes place in a cell that already lacks a functional copy of the gene, expression of the tumor suppressor gene is completely abrogated and cancer is likely to result. It has subsequently been shown that loss of the second allele can occur by a variety of mechanisms, including point mutation in the allele, deletion of the allele or the chromosomal segment where it resides, deletion of the entire chromosome containing the allele, or mitotic recombination resulting in replacement of the normal allele by the mutant allele. When the normal allele has been completely lost, the cell and its progeny contain only the single abnormal allele. This is called loss of heterozygosity.

Tumor suppressor genes are frequently located in areas of the genome that are deleted in cancer. The areas of chromosomal loss can be limited to small deletions of a few hundred base pairs or encompass a whole chromosome arm or even an entire chromosome. By examining a large number of tumors, the minimal region of loss can be defined as the common region, which is deleted in all tumors of the type under investigation. Candidate tumor suppressor genes within the boundaries of this area can then be further interrogated for the presence of inactivating mutations in the remaining allele. Confirmation of the candidate gene as a *bona fide* tumor suppressor gene involves complex *in vitro* and *in vivo* experiments, such as demonstrating that (1) loss of the gene product leads to increased ability to form colonies in soft agar, (2) the presence of mutation, deletion, or hypermethylation along with the absence of the gene product in primary tumors, and (3) loss of the gene correlates with increased tumorigenicity in mouse models. In addition to loss of genetic material and inactivating mutations, it is now widely recognized that DNA methylation, discussed earlier, is an alternative method of silencing tumor suppressor genes.

Many tumor suppressor genes are key components of the cell cycle. One of the most widely studied tumor suppressor genes is p53, and it is inactivated most commonly by mutation in more than half of human cancers. It is a DNA-binding protein that regulates transcription of numerous genes and plays a critical role in cell-cycle arrest and induction of apoptosis following DNA damage. For these reasons, it has been entitled the guardian of the genome. Levels of p53 are rapidly elevated in response to DNA damage. This leads to increased transcription of p53 target genes, such as p21 and GADD45, which function in cell-cycle arrest and DNA repair, respectively. The half-life of p53 is short (about 20 minutes) and is rapidly degraded following completion of DNA repair. If the DNA repair is unsuccessful, p53 directs cell death by activating BCL2-associated X protein (BAX), a key component of the apoptotic cascade (Fig. 6-45). It is clear then that loss of functional p53 can have devastating consequences for maintaining integrity of the genome. Without p53, mutagenic DNA damage goes unchecked, the cell proceeds through division, and the mutation becomes fixed in the genome.

290

292

**Fig. 6-44 Schematic illustration of the pathogenesis of retinoblastomas (RBs) and the “two hit” hypothesis.** Two mutations of the RB gene lead to neoplastic proliferation of the retinal cells. In the familial form (*left*), all somatic cells have one mutant copy of the RB gene inherited from a carrier parent. The second mutation affects the RB locus in one of the retinal cells after birth. In the sporadic form (*right*), both RB mutations are acquired by the retinal cells after birth. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Another widely studied tumor suppressor gene is the retinoblastoma gene. As described earlier, RB is a target for inactivation both in germline and somatic cells and, like p53, plays an important role in cell-cycle control. In quiescent cells, RB is hypophosphorylated and active. When RB is hyperphosphorylated and inactive, the cell can proceed through the G<sub>1</sub>/S transition. Control of proper RB function and phosphorylation status involves a host of other genes, including p16INK4a, cyclin D, and CDK4. Therefore a defect in any one of these gene products disrupts the RB pathway and leads to unregulated progression through the cell cycle.

**Fig. 6-45 The role of p53 in maintaining integrity of the genome.** DNA damage or hypoxia activate normal p53, leading to G<sub>1</sub> arrest and induction of DNA repair by upregulation of p21 and GADD45, respectively. Successful DNA repair allows cells to proceed through the cell cycle. If DNA repair fails, BCL2-associated X protein (BAX) promotes apoptosis. In cells with loss or mutation of p53, DNA damage does not induce cell-cycle arrest or DNA repair. The genetically damaged cells proliferate and may eventually give rise to malignant neoplasms. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

Although the classic definition of a tumor suppressor gene dictates that both alleles must be inactivated (through loss, mutation, or promoter methylation), recent evidence suggests that for certain genes inactivation of only one copy is sufficient for tumor growth (haploinsufficiency). Haploinsufficiency can contribute to tumor development by a number of mechanisms. One mechanism is a simple gene-dosage effect in which half the normal amount of a protein is insufficient to maintain the normal homeostatic balance in the cell. Alternatively, a mutation in one allele can give rise to a dominant-negative protein whereby the abnormal protein blocks the function of the normal protein produced by the remaining wild-type allele. A third mechanism occurs when a mutation in one allele of a tumor suppressor gene decreases the amount of normal protein in a cell, which may in turn influence other pathways that may have concurrent abnormalities.

### 6.12.2 ONCOGENES

Oncogenes are derived from proto-oncogenes—normal cellular genes that regulate cell growth and differentiation. Proto-oncogenes encode products involved in diverse pathways and include molecules such as growth factors and their receptors, cell-cycle regulators, DNA-binding proteins, transcription factors, protein kinases, and others. Oncogenes were first identified as RNA tumor virus proteins. Later it was discovered that normal cells have the equivalent gene products.

There are a number of ways in which oncogenes can be abnormally activated to promote tumor growth. The genomic region containing the gene can be amplified, resulting in dramatically increased copy number. For example, the N-MYC oncogene can be amplified up to 100 times in human neuroblastomas. Oncogenes can undergo mutations that cause constitutive activation of the gene. In these cases, the gene is always “turned on” and is unresponsive to inhibitory signals. This scenario is often the case for cell surface receptors, such as the epidermal growth factor receptor (EGF-R) in carcinomas. Many tyrosine kinase receptors have activating mutations that result in constitutive activation even in the absence of ligands. Tumor cells can also produce large amounts of stimulatory molecules along with their cognate receptors, forming a growth-promoting autocrine loop. All of these mechanisms serve to drive proliferation and render the cell unresponsive to normal inhibitory signals.

The prototype of signal transduction oncogenes is the RAS family of guanine triphosphate binding proteins (G proteins). There are several members of this family, including HRAS, KRAS, and NRAS. In normal cells, RAS transmits growth stimulatory signals from outside the cell to the nucleus, ultimately activating transcription of genes for cell-cycle progression. RAS alternates between an active and inactive state in its normal location on the cytoplasmic side of the cell membrane where it is closely associated with farnesyl transferase. Inactive RAS binds guanine diphosphate (GDP). Upon receiving a stimulatory signal from a growth factor, RAS exchanges GDP for guanine triphosphate (GTP). RAS bound to GTP is the active form, which triggers the RAS–RAF–mitogen-activated protein kinase (MAPK) pathway and results in transcription of genes that promote cell division (Fig. 6-46). The activation of RAS is normally short lived, as RAS has an intrinsic GTPase that hydrolyzes GTP to GDP and converts RAS to its inactive state. In many cancers, RAS is constitutively activated either by mutations in RAS itself or by failure of the GTPase to inactivate RAS. RAS family members, the farnesyl transferase anchor to the plasma membrane, and other components of the signal transduction pathway are all attractive molecular targets for therapeutic intervention in cancer patients.

### 6.12.3 DEFECTS IN DNA REPAIR

Defects in DNA repair enzymes are one cause of mutations and genomic instability. If mutations inactivate tumor suppressor genes and activate oncogenes, the cell has a selective growth advantage. Specific types of

## Pathologic Basis of Veterinary Disease, 4th Edition

DNA repair mechanisms have evolved to repair specific DNA lesions. Mismatch repair enzymes, such as MLH1 and MSH2 proofread DNA, much like the “spell check” function on a computer, to locate and fix single nucleotide mismatches that occur on a regular basis. For example, if an adenine is mistakenly paired with a guanine during DNA replication, this error will be recognized and corrected.

It is well recognized that exposure to ultraviolet light leads to cross-linking of pyrimidine residues and formation of pyrimidine dimers. These lesions require a large cohort of DNA repair proteins to perform a nucleotide excision repair procedure. This process is similar to the “cut and paste” function of a computer in which the dimer is excised and the correct nucleotides are replaced and ligated in its stead. As discussed earlier, p53 levels rise in response to DNA damage from any number of agents and give the cell time to carry out the repair processes.

Additional DNA repair genes include ATM, BRCA1, and BRCA2 in humans. Failure of DNA repair of any type can lead to the mutation becoming fixed in the genome and passed on with subsequent rounds of cell division. When the DNA repair gene itself is defective, either through mutation, promoter methylation, or genomic loss, the result is a myriad of mutations throughout the genome with widespread genomic instability and increased cancer susceptibility.

293

294

**Fig. 6-46 Model for action of RAS genes.** When a normal cell is stimulated through a growth factor receptor, inactive (guanine diphosphate [GDP]-bound) RAS is activated to a guanine triphosphate (GTP)-bound state. Activated RAS recruits RAF and stimulates the mitogen-activated protein kinase (MAPK) pathway to transmit growth-promoting signals to the nucleus. In cancer, mutated RAS is permanently activated because of the inability to hydrolyze GTP, leading to continuous stimulation of cells in the absence of an external trigger. The anchoring of RAS to the cell membrane by the farnesyl moiety is essential for its action. GAP, GTPase-activating protein. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

### 6.13 ANIMALS AND CANCER

#### 6.13.1 ANIMAL MODELS OF CANCER

Animal models have been and remain critically important tools for understanding the cause of human cancer and for testing cancer therapeutic agents. Animal models of cancer include both experimentally induced and naturally occurring. In experimentally induced cancer models, administration of carcinogenic substances or transplantation of human cancer cells results in *de novo* development of cancer in test animals. Naturally occurring models of cancer rely on the spontaneous development of tumors in the test animal.

##### 6.13.1.1 EXPERIMENTALLY INDUCED TUMORS

A major advantage of experimental model systems is the rapid and reproducible induction of cancer in a very large proportion of experimental animals. Rodents, mice in particular, are often used for such studies. Mice are small and relatively inexpensive to maintain. Moreover, mice reproduce rapidly and their genetics are highly defined and readily manipulated. The mouse genome has recently been sequenced, essentially in its entirety, and detailed comparative maps of the human and mouse genomes have been developed. Many inbred mouse strains, each consisting of genetically identical or syngeneic individuals, are available. Syngeneic mice readily accept tissue grafts from each other. Genetic homogeneity of syngeneic mice tends to standardize responses and thus reduce the numbers of animals required for studies. A number of inbred mouse strains have been developed that are particularly suited to specific needs in cancer research. For instance, Sencar mice are highly susceptible to tumors of keratinocyte origin and are thus employed for many skin carcinogenesis studies. Nude mice, which are profoundly immunodeficient, accept tumor or normal tissue grafts from other species and provide an environment in which these xenografts can be maintained, manipulated, and studied. Differences in strain susceptibility to different experimentally induced cancers have been exploited to identify modifier genes that dramatically affect tumor incidence. With the advent of effective means for creating genetically engineered mice, specific genes of interest can be introduced into or inactivated in the mouse genome. A gene introduced into the mouse genome is generally termed a transgene. A mouse lacking a functional normal gene is a knockout for that gene. Moreover, the timing, location, and level of gene expression in genetically engineered mice can now be precisely controlled, thus allowing gene expression to be turned on or off in particular tissues as required for specific studies. Gene expression modulated in this fashion is termed conditional gene expression.

294

295

Conventional inbred mice have been used extensively to determine the carcinogenicity of chemical and physical agents and to test the safety and efficacy of anticancer therapeutics. Studies in mice, particularly studies of chemically induced skin cancer, have been critical in defining the stages of carcinoma progression. Genetically engineered mice have been essential for identifying the mechanisms by which specific genes act to retard or enhance tumor development, growth, and spread. However, mice have several inherent shortcomings as models of human cancer. The genetic homogeneity of inbred mice does not reflect the high degree of genetic diversity within the general human population. The spectrum of experimentally induced tumors in mice differs from the spectrum of naturally occurring tumors in humans. Moreover, experimentally induced tumors in mice rarely metastasize; in humans, on the other hand, tumor metastasis is of overwhelming importance. Finally, the short life span and small size of mice make them less than ideal for long-term testing of tumor therapies.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 6.13.1.2 NATURALLY OCCURRING TUMORS

Several naturally occurring cancers in animals, including avian leukosis, bovine lymphoma, and feline leukemia, have provided invaluable information about the cause, transmission, and prevention of virally induced cancers. However, virally induced cancers do not appear to account for a large proportion of human cancers. Recently the dog has become the focus of increasing attention as a useful animal model of nonviral human cancers. The recent sequencing of the canine genome and comparative alignment with human and murine genomes enhance the usefulness of dogs as a naturally occurring cancer model.

The age-adjusted cancer incidence in dogs is 381 per 100,000; this is comparable with the cancer incidence in humans. With the large number of pet dogs in this country, many cancer cases are thus available for entry into clinical trials. Like humans, dogs are outbred. Moreover, dogs share a common environment with humans and are exposed to many of the same carcinogens. As in humans, many canine tumors metastasize widely. Because tumors in dogs progress more rapidly than human tumors, studies can be completed within a reasonable time frame. On the other hand, the time course of tumor development is sufficiently long to allow meaningful comparison of response times in different treatment groups. Because dogs are relatively large, they provide abundant tumor tissue for diagnostic and experimental purposes. In addition, many therapeutic approaches that are difficult to test in small rodents can readily be examined using larger dogs. Clinical trials in dogs are much easier to instigate and much cheaper to carry out than comparable studies in humans. Many dog owners are enthusiastic participants in clinical trials that may benefit their pets. Tumor types for which dogs are particularly good models of human cancer include osteosarcoma and lymphoma.

### 6.13.2 CLINICAL ONCOLOGY

#### 6.13.2.1 HISTOPATHOLOGIC DIAGNOSIS

A definitive diagnosis of cancer is frequently obtained by standard histopathology and/or cytology from incisional or excisional biopsies or aspirates. Biopsy specimens are analyzed by routine hematoxylin and eosin (H&E) staining for histopathologic evaluation, and by Wright's stain or Diff-Quik for aspirates. Cells are scrutinized for features of malignancy, including abnormal morphology, evidence of invasion and/or metastasis, high mitotic index, presence of abnormal mitoses, high nuclear:cytoplasmic ratio, and absence of encapsulation. The degree of differentiation is evaluated. Malignant neoplasms are frequently poorly to moderately differentiated, and some may be so anaplastic that the cell of origin cannot be determined. Abnormal structures or cellular products may also provide clues to the presence of malignancy.

Special staining techniques may be used to aid in the diagnosis of some tumors. For example, immunohistochemistry can establish if a lymphoma originates from B lymphocytes or T lymphocytes (Fig. 6-47). This knowledge may be useful to the clinician in designing treatment or delivering a prognosis. The type of intermediate filaments present in an undifferentiated malignancy can indicate if the tumor is of epithelial (positive for cytokeratin staining) or mesenchymal (positive for vimentin staining) origin. Some neoplasms, such as mesotheliomas and synovial cell sarcomas, are often positive for both cytokeratin and vimentin. Squamous cell carcinomas that have undergone epithelial-to-mesenchymal transformation will have areas positive for one stain or the other, and the transition areas may be positive for both. An exhaustive list of antibodies is beyond the scope of this chapter, but immunohistochemical staining is becoming a widely used tool that assists the pathologist in providing a more complete diagnosis in cases in which routine H&E evaluation is limited.

295

296

**Fig. 6-47 Lymphoma, liver, dog.** Note the neoplastic lymphocytes invading the liver. The malignant cells are immunohistochemically positive for CD3 (*brown color*), indicating a T-lymphocyte neoplasm. The surrounding hepatocytes are not labeled. Immunohistochemistry. (Courtesy Dr. D.F. Kusewitt, College of Veterinary Medicine, The Ohio State University.)

Histochemical stains can also aid in diagnosis. Poorly differentiated canine mast cells may have granules that are not clearly visible by H&E staining. Staining with toluidine blue often highlights the granules and confirms the diagnosis in otherwise challenging cases.

### 6.13.2.2

#### CLONALITY ASSAYS

Although cells can exhibit some degree of heterogeneity within a tumor as a result of clonal selection (see previous discussion), all of the neoplastic cells originated from expansion of a single transformed cell. *Clonality* can be assessed using the HUMARA (human androgen receptor assay) method in females who are polymorphic at the X-linked androgen receptor locus (Fig. 6-48). Other X-linked genes that can be interrogated include G6PD or PGK. Because females have random inactivation of one X chromosome in each cell, clonality can be demonstrated by showing that each cell within a tumor population has the same X chromosome inactivated (thus the need to use polymorphic markers). If the tumor population has equal distribution of inactivated X chromosomes, it is not monoclonal. These assays have not been well established in companion animals.

Clonality can be determined by a different method in lymphoid malignancies. Sometimes it is difficult to distinguish benign lymphoid hyperplasia from lymphoma by morphology alone. Establishing that the lymphocyte population is clonal gives more weight to the diagnosis of a malignancy. This can be done by analyzing the lymphocytes for T- or B-lymphocyte receptor rearrangement using the polymerase chain reaction (PCR). If the entire lymphocyte population has a single rearrangement, this is indicative of a clonal population. Conversely, if each lymphocyte has a different receptor rearrangement, this indicates a nonclonal population, which is more consistent with a reactive specimen. It must be remembered that the presence of a

## Pathologic Basis of Veterinary Disease, 4th Edition

clonal population does not, by itself, mean that the specimen is a malignancy. Some nonneoplastic conditions, such as canine ehrlichiosis, can give rise to clonal lymphocyte populations. Therefore results need to be interpreted in conjunction with clinical signs and other clinicopathologic data.

296

297

**Fig. 6-48 Diagram depicting the use of X-linked isoenzyme markers to assess monoclonality of tumors.** Because of random X-inactivation, all females are mosaics with two cell populations (G6PD isoenzyme A or B in this case). Monoclonal neoplasms are composed of cells that contain the active maternal ( $X_A$ ) or the paternal ( $X_B$ ) X chromosome, but not both. These assays can only be used in females who are heterozygous at the X-linked marker being tested. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

6.13.2.3

### OTHER MOLECULAR DIAGNOSTIC TECHNIQUES

A full description of molecular techniques used in cancer diagnosis is beyond the scope of this chapter. However, it is certain that their use will become more widespread and commonplace in veterinary medicine. Cytogenetic analysis can be a useful tool for diagnosis, determining the presence of residual disease after treatment, stratification of high- and low-risk patients. The discovery of recurrent chromosomal abnormalities and translocations, particularly in leukemias and lymphomas, will aid in diagnosis and understanding the pathogenesis of these diseases.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The increasing use of microarrays for global gene expression analysis in the research setting will undoubtedly lead to identification of panels of specific biomarkers that can be used for diagnosis in the future. Microarrays, which allow the measurement of thousands of genes simultaneously in a single sample, are already available for dogs and horses, and it is anticipated that other species will be added to the list. Large-scale studies using carefully selected tumor samples will be necessary to identify significant diagnostic and prognostic changes in gene expression patterns, which can be applied to individual tumors to provide important information to the clinician. Likewise, the advancement of proteomics for the large-scale interrogation of protein expression in tumors will add to our diagnostic armamentarium.

Finally, identification of genes involved in inherited cancers can be accomplished through the detailed analysis of well-described pedigrees, particularly in certain cancer-prone breeds. As is the case in humans, the elucidation of these genes is important not only in the diagnosis and screening of high-risk animals but also in providing insight into the pathogenesis of sporadic tumors.

### 6.13.2.4 GRADING

A tumor grade is assigned by the pathologist to provide some indication of how similar or dissimilar the neoplastic cells are to their normal counterparts. The underlying assumption is that this provides some indication about biologic behavior. This is not universally true, however, and experience has demonstrated that tumor stage (see next section) is sometimes a more useful parameter. Grading schemes vary depending on the tumor type. The ideal scheme incorporates criteria that are easily identified on an H&E stained section, and the grade is strongly linked to prognosis or response to therapy.

All grading schemes evaluate the degree of differentiation of tumor cells. The tumor grade classifications usually include well-differentiated (cells appear very similar to normal cells), moderately differentiated (somewhat similar to normal cells), and poorly differentiated (anaplastic) cells. These categories translate to low, medium, and high grade, or grades I, II, and III, respectively. Other criteria that may be included in grading schemes include the mitotic rate (i.e., the number of mitotic figures in ten 40 $\times$  fields), the degree of necrosis, location and invasiveness of the tumor, and overall cellularity. To be biologically relevant, the grading system for a particular tumor type should be based on objective criteria that can be assessed on routine sections with high concordance between different evaluators and provide the clinician with useful information. As such, criteria need to be periodically reevaluated in light of new discoveries and diagnostic capabilities.

### 6.13.2.5 STAGING

Tumor stage gives an indication of the extent of tumor growth and spread. In general, staging guides the clinician in developing a therapeutic plan and offering an estimate of prognosis to the client. One of the most widely used schemes is the TNM system, which is based on the size of the primary tumor (T), degree of lymph node involvement (N), and extent of metastasis (M). Within each category, a number is assigned based on clinical, diagnostic, and histopathologic evaluation. A designation of T<sub>0</sub> is given to carcinoma in situ, whereas T<sub>1</sub> to T<sub>4</sub> indicate increasing size of the primary tumor. N<sub>0</sub> indicates the absence of detectable lymph node involvement, whereas N<sub>1</sub> to N<sub>3</sub> indicate progressive involvement. Similarly, M<sub>0</sub> signifies no detectable metastasis, whereas M<sub>1</sub> and M<sub>2</sub> indicate metastasis to one and two organs, respectively.

Overall, TNM staging provides a standard measurement by which the natural course of disease and impact of treatment modalities can be compared. Increased availability of more sophisticated diagnostic testing, such

## Pathologic Basis of Veterinary Disease, 4th Edition

as computerized tomography (CT) and magnetic resonance imaging (MRI), as well as more sensitive histologic detection, such as the use of immunohistochemistry for cytokeratin to detect micrometastases in lymph nodes of patients with carcinoma, may influence comparisons of studies among investigators.

6.13.2.6

### SURGICAL MARGINS

Typically, excisional biopsies are performed with the intent of complete removal of the tumor mass to effect a cure or greatly reduce tumor burden. Histologic evaluation of surgical margins has long been a valuable service provided by the diagnostic pathologist. Margins of the tumor are evaluated microscopically for the presence or absence of tumor cells to confirm that the tumor was completely excised. Residual malignant cells at the surgical site may warrant a second surgical procedure.

297

Evaluation of margins is not always straightforward. Sometimes it is difficult for the pathologist to properly orient the gross specimen with respect to lateral, deep, and superficial margins. At other times it may be difficult to distinguish true surgical margins from those produced at trimming. This uncertainty can be diminished if the surgeon marks the tumor with ink (preferable) or sutures upon removal of the tumor from the body, and indicates in the pathology request which margins (lateral, deep) are so marked. In select circumstances, evaluation of surgical margins on frozen tissue sections while the patient remains under anesthesia may be beneficial. If residual tumor cells are present at the margins, the surgeon then has the opportunity to immediately make a wider excision without subjecting the patient to a second operative procedure. It is important to realize that having clean surgical margins on a histologic slide does not guarantee that the patient is free of tumor. Neoplasms are three-dimensional lesions that often have irregular growth patterns. Only a portion of the mass is examined in any one section, and although that particular section may have clean margins, other portions of the mass may not. In addition, multifocal or multicentric lesions may not be submitted to the pathologist. Lastly, lymphatic or hematogenous spread may not be evident on the section or sections examined.

298

The American College of Veterinary Pathologists has formed an Ad Hoc Committee on Oncology to provide guidance on new diagnostic techniques in oncology and develop written guidelines to promote more consistent methods for tumor grading and reporting of margins.

Taken together, the tumor type, grade, stage, and completeness of excision are used by the clinician to develop the most appropriate treatment plan for the patient. As we learn more about the molecular pathogenesis of certain tumors, the need for specialized diagnostic tests will certainly increase. Targeted molecular therapies will be effective only if the target is present in the patient's tumor. For example, a compound that is designed to be active against the internal tandem duplication (ITD) of c-kit in canine mast cell tumors will probably not be very effective if administered to patients without the ITD. Open lines of communication between clinicians and pathologists are vital to the integration and use of such knowledge.

## 7 Chapter 7 Alimentary System\*

HOWARD B. GELBERG

### 7.1 INTRODUCTION

The alimentary system is a long and complex tube that varies in its construction and function among animal species. For example, herbivores need fermentation chambers (either a rumen or expanded cecum) for the digestion of cellulose, a feature not present in carnivores. Although a large variety of gastrointestinal disturbances are clinically important in all species of animals, the predominant form of disease varies by species. Pet carnivores, partly because of their long life span, effective vaccines, and a lifestyle and diet similar to that of human beings, have alimentary neoplasia develop far more often than herbivores. Meat, milk, and fiber-producing animals (ruminants and pigs) are host to a variety of infectious diseases that are largely resistant to vaccines. These pathogens may have evolved as a result of the herding instinct of these animals and the opportunity for pathogens to mutate within a large socially structured host population. Equids are most prone to displacements of alimentary viscera.

A large part of the practice of veterinary medicine is devoted to the diagnosis and treatment of alimentary disorders. Many of the newer molecular and imaging tools have been designed specifically to increase the clinician's ability to make accurate diagnoses of the varied conditions of the alimentary system. Additionally, every physical examination includes the opportunity for a fecal analysis that allows the clinician a window into the functioning of the alimentary system as a whole.

Tools such as the polymerase chain reaction (PCR) allow the clinician to rapidly diagnose an infectious cause of enteritis without having to culture the organism in the traditional manner. Diagnosis of the cause of an infectious disease of the alimentary system can also be made after biopsy from paraffin-embedded tissue by immunohistochemical staining or by in situ hybridization that allows demonstration of the pathogen within target cells.

With the advent of fiberoptic endoscopes combined with laparoscopy, a thorough knowledge of normal and abnormal anatomy of the entire alimentary system is of clinical importance in disease diagnosis. This knowledge is now a necessity in clinical practice because gastrointestinal lumens, from the oral mucosa through the esophagus, stomach, duodenum, and the large colon, can be directly viewed in the live animal. With a small abdominal incision and insertion of a fiberoptic laparoscope, the entire serosal surface of the abdominal viscera can be viewed and sampled.

#### 7.1.1 STRUCTURE AND FUNCTION

The most important point to keep in mind when examining the alimentary system is that normal mucosal and serosal surfaces should be smooth and shiny. The exception to this rule is the rumen, in which the papillae may normally have a roughened, towel-like surface appearance. When they do not, animals should be examined thoroughly to determine why they deviate from normal. The function of the alimentary system in its entirety is to take ingested feedstuffs, grind them and mix them with a variety of secretions from the oral cavity, stomach, and intestines (digestion) and absorb the constituent nutrients into the blood stream and lacteals. Undigested ingesta, effete neutrophils, fresh (hematochezia) or digested (melena) blood, and excess secretions are passed from the body into the alimentary lumen and thus become a component of the feces. The quality and quantity of the feces is often an early indicator of alimentary dysfunction, as is regurgitation and vomiting.

## Pathologic Basis of Veterinary Disease, 4th Edition

\* Previous contributions to this chapter were authored by Dr. H. Van Kruningen of the Department of Pathobiology, University of Connecticut.

301

### 7.1.2 PORTALS OF ENTRY

302

There are limited numbers of ways that pathogenic agents gain entry into the alimentary system (Box 7-1). The most common, of course, is through ingestion. However, under certain circumstances pathogens may be coughed up by the lungs and swallowed. Systemic blood-borne infections of viruses (viremia), bacteria (bacteremia), and systemic toxins (septicemia and toxemia) may make their way through the blood stream and attach to specific receptors on the epithelial lining cells of the alimentary system. Parasites may migrate through various regions of the body to find a home within the mucosa or free in the lumen of the alimentary tract.

### 7.1.3 DEFENSE MECHANISMS

Considering the types of materials that are ingested by domestic animals, it is significant to note that they are not constantly ill. This resistance to disease occurs because the alimentary system is well suited to protect itself against most potentially pathogenic insults (Box 7-2). These protective mechanisms include oral secretions such as saliva; “normal” resident flora and fauna; the gastric pH; opening of tight junctions between cells to allow macromolecules such as immunoglobulins into the lumen; vomiting; extraintestinal secretions from the liver and pancreas; intestinal proteolytic enzymes, phagocytes, and other effector cells within the submucosa, which are exuded into the alimentary lumen; the high rate of epithelial turnover; increased peristalsis resulting in diarrhea; Paneth cells; and the immune system. Paneth cells produce antimicrobial peptides and proteins, including lysozyme and secretory phospholipase A<sub>2</sub>. They also produce  $\alpha$ -defensins (cryptdins).

- Paneth cells
- Adaptive immune system

### 7.2 DISEASES

#### 7.2.1 ORAL CAVITY

##### 7.2.1.1 INTRODUCTION

Examination and evaluation of the oral cavity is one of the many places where the practice of pathology and clinical medicine merge. This result is because the oral cavity can be examined by the clinician or pathologist using the same criteria for abnormality. The same can be said of the rectal mucosa.

##### 7.2.1.2 STRUCTURE AND FUNCTION

The physiologically normal oral mucosa is smooth, shiny, and pink. In animals in which the oral mucosa is heavily pigmented (melanosis), assessment of circulatory function (capillary refill time) and color as an indicator of red blood cell concentration (packed cell volume) can be difficult. In these cases, examination of conjunctiva, rectal, and urogenital mucosa can be substituted. The oral cavity is where ingested materials are masticated; mixed with digestive enzymes, such as saliva; and passed on through the oropharynx to the esophagus.

##### 7.2.1.3 DEFENSE MECHANISMS

Defense mechanisms of the oral cavity include the taste buds, which reject potentially toxic materials based on taste and tongue feel, an indigenous bacterial flora that occupy attachment sites of pathogens, and saliva ([Box 7-3](#)). Saliva provides a flushing action so potential pathogens are cleared from the oropharynx. Saliva also forms a protective coating of the mucosa and contains antimicrobial lysozyme and immunoglobulins. Neutrophils at the end of their life span are eliminated by migrating through the alimentary tract. This includes the oral cavity. In their absence, stomatitis results.

##### 7.2.1.4 DEVELOPMENTAL ANOMALIES

A variety of developmental abnormalities occur in the oral cavity. Some are incompatible with life unless surgically corrected. Of these congenital lesions, only a few have a proven hereditary component. Most are idiopathic. Thorough physical examination of neonates must include examination of the oral cavity for these defects.

302

## 7.2.1.4.1

**Box 7-3 Defense Mechanisms in the Oral Cavity**

- Taste buds that reject potentially toxic materials based on taste and tongue feel
- Indigenous bacterial flora that occupy attachment sites of pathogens
- Saliva
- Flushing action so potential pathogens are cleared from the oropharynx
- Protective coating of the mucosa
- Contains antimicrobial lysozyme and immunoglobulins

Palatoschisis or cleft palate and cheiloschisis or cleft lip are among the most common developmental abnormalities of the oral cavity. Cheiloschisis is sometimes referred to as “hare lip,” because this is a normal feature of the rabbit. It is a failure of fusion of the upper lip along the midline or philtrum. Palatoschisis can be genetic or toxic in origin. It results from a failure of fusion of the lateral palatine processes. It can be caused by steroid administration during pregnancy in primates, including human beings. Depending on the size of the defect, which may involve only the soft palate or both the soft and hard palates (Fig. 7-1), the lesion may be surgically correctable. It is a matter of some ethical concern whether to correct such defects without also sterilizing the patient, because the potential for cleft palate to have a genetic cause is present. Important sequelae to the host from cleft palate are starvation due to an inability to create a negative pressure in the mouth and resultant failure to suckle and aspiration pneumonia, because no effective separation is present between the oral and nasal cavities.

## 7.2.1.5

**STOMATITIS AND GINGIVITIS**

Stomatitis and gingivitis refer to inflammation of the mucous membranes of the oral cavity and gingiva, respectively. Because the oral cavity is constantly bombarded with ingested substances that are moved around by the tongue, the final result of a variety of insults to the lining of the oral cavity is a loss of mucosa—erosions, ulcerations, and necrosis. Thus, although inflammation is apparent, clues as to the initiating process may be absent. Lesions are classified as macules, papules, vesicles, erosions, and ulcers. These lesions can be caused by infectious agents, particularly viruses, chemical injury, trauma, intoxicants, autoimmune disease, and by systemic diseases. They often result in anorexia due to painful mastication. Hypersalivation (ptyalism) is also apparent, whether from overproduction or lack of swallowing. In the cat, gingivitis is the first and most consistent sign of feline immunodeficiency virus infection associated with a reduction in CD4 lymphocytes, thymic atrophy, and lymph node atrophy.

**Fig. 7-1 Palatoschisis and cheiloschisis, hard and soft palate, puppy.** The lateral palatine processes have failed to fuse during the first trimester of gestation (palatoschisis). In dogs, palatoschisis has been attributed to genetic abnormalities, excessive intake of vitamin A during gestation, and the administration of cortisone during gestation. The upper lip is also cleft (cheiloschisis). (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

### 7.2.1.6

#### VESICULAR STOMATITIDES

The vesicular stomatitides are listed in [Table 7-1](#). Blistering or vesiculation of the oral epithelium is present early in the course of these diseases. They are all virus-induced, and all have identical appearances at gross and histopathologic examination. None of these conditions is fatal. They produce great economic loss in the affected animals because of poor weight gain and sometimes abortions in gravid females. The exact cause of the abortions is unknown, but it is probably related to the stress induced by the painful oral, cutaneous, and pedal (hoof or foot) lesions. Secondary bacterial invaders, both gram-negative and gram-positive, of these lesions can result in endotoxemia. Several diseases, such as foot-and-mouth disease and vesicular exanthema, affect the coronary bands of the digits and interdigital clefts, resulting in lameness. Some of these diseases (foot-and-mouth disease, vesicular exanthema, swine vesicular disease) are exotic to the United States and thus are reportable to state or federal authorities, or both, if suspected by the examining clinician or pathologist. This requirement is due to the great expense involved in eradicating these diseases from the United States and their potential use as agents of agroterrorism. Nontariff export barriers often arise from the presence of infectious agents in livestock that are foreign to countries with which we trade. These

303

304

## Pathologic Basis of Veterinary Disease, 4th Edition

restrictions are designed to prevent introduction of highly contagious agents, such as foot-and-mouth disease, into resident animal populations.

Table 7-1 Vesicular Stomatitides

Disease	Cause	Ruminant	Pigs	Horses
Foot-and-mouth disease	Picornavirus	+	+	–
Vesicular stomatitis	Rhabdovirus	++	+	+
Vesicular exanthema of swine	Calicivirus	–	++	–
Swine vesicular disease	Enterovirus	–	++	–

+ = Species in which disease occurs; – = species in which disease does not occur.

The gross lesions of the vesicular stomatitides are epitheliotropic. Fluid-filled vesicles are present in the oral cavity, lips, rostral plate, and tongue (Fig. 7-2, A). Entry of virus in these cases is most likely oral into areas of temporary loss of mucosa due to normal mastication and trauma. The viruses are cytolytic, and the resultant release of virus from cells infects neighboring cells. The lesions enlarge centripetally, forming vesicles. Bullae result from vesicle coalescence. The epithelium covering large bullae easily ruptures with handling. Subsequently, ulcers are created. These ulcers are typically hyperemic (Fig. 7-2, B). Viremia, often transient, sometimes occurs.

Similar vesicular lesions occur in the nasal mucosa, particularly in pigs with vesicular exanthema and in the proximal epithelium of the alimentary system (esophagus and rumen) of cattle with foot-and-mouth disease. Some animals have conjunctivitis and vesicular dermatitis of the teats and vulva. Microscopically, the lesions of these four diseases (foot-and-mouth disease, vesicular stomatitis, vesicular exanthema, and swine vesicular disease) are similar. Virus-induced, intracellular edema progresses to cell swelling of the stratum spinosum. Cell lysis and intercellular edema and vesicles result. The epithelium overlying the virus-rich vesicular fluid contains large amounts of intracellular virus. Even slight friction can rupture vesicles and bullae, creating an ulcer. Healing progresses from the normal fibrin and/or neutrophil rich acute stages to the more chronic stages of granulation.

Lesions and signs of the vesicular stomatitides include vesicles, bullae, oral epithelium that detaches to leave a raw, ulcerated surface, ptyalism, lameness, fever, and anorexia. The lesions develop as a result of rupture of initially infected cells and centripetal spread of virus to adjacent susceptible epithelium and multiple repeats of this infectious, lytic cycle. The vesicular stomatitides are tentatively diagnosed based on the clinical signs and lesions resulting from oral and nasal ulceration, conjunctivitis, and ulceration of the genitalia and mammary gland. Lameness is secondary to hoof involvement that is focused at the coronary band. Definitive diagnosis is important and is performed at federal laboratories equipped to rapidly respond to putative outbreaks. Federal quarantine of infected herds is an important control mechanism, followed by eradication, slaughter, and carcass disposal.

304

305

**Fig. 7-2 Cutaneous vesicles, vesicular exanthema, snout, pig. A,** Vesicles, both intact (upper vesicle) and ruptured (lower vesicle), are present on the planum rostrale and are caused by the infection of injured mucosal epithelial cells with vesicular exanthema of swine virus, a calicivirus. **B,** Ruptured vesicles with cutaneous ulceration, vesicular exanthema (later stage of the disease). Note the ruptured vesicles which can cause pain resulting in inappetence. (**A,** From Gelberg H, Lewis RM: *Vet Pathol* 19:424-443, 1982. **B,** Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.1.7

### SPECIFIC VESICULAR DISEASES

Foot-and-mouth disease is an extremely important disease worldwide but has not appeared in U.S. livestock since 1929, when it was eradicated after an outbreak in California. It is characterized in its early stages by vesicles in the planum nasale, in the oral cavity, and tongue. Fluid from ruptured vesicles spreads to areas of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

abraded skin; for example, that of mammary gland. The coronary bands of the hooves can also be affected. Coronary band vesiculation may eventually lead to sloughing of the hoof. Although this disease is not fatal, the pain and accompanying inappetence lead to weight loss. If allowed to heal, the hoof will regrow into a ball-like structure. Young animals with foot-and-mouth disease frequently have a viral myocarditis.

Vesicular stomatitis is common in calves, but does not occur in sheep or goats. In northern latitudes, it is generally a warm weather disease, suggesting that insects act as vectors. As the name implies, vesicles in the oral cavity characterize the disease. Clinically the disease is often recognized by inappetence in the affected animal, accompanied by ptyalism.

Vesicular exanthema is a specific disease of pigs that is indistinguishable clinically and pathologically from foot-and-mouth disease. This disease is uniquely American and was believed eradicated from pigs in 1956 through enactment of federal laws requiring the cooking of garbage fed to pigs. The evidence indicates that vesicular exanthema of swine serovars are variants of San Miguel sea lion virus. This latter marine calicivirus occurs in coastal sea lion and fur seal populations from California to Alaska (Fig. 7-3).

Swine vesicular disease is indistinguishable from the other vesicular diseases and is exotic to the United States.

7.2.1.8

### EROSIVE AND ULCERATIVE STOMATITIDES

Erosions are defined by a loss of part of the surface epithelium, whereas ulcers are full-thickness epithelial losses exposing the basement membrane. Thus erosions may progress to ulcers that may become perforating ulcers. Erosive and ulcerative stomatitis can have a variety of causes. Agents responsible include the viruses of bovine viral diarrhea (BVD) (Fig. 7-4), rinderpest, malignant catarrhal fever (Fig. 7-5), feline calicivirus, equine viral rhinotracheitis, and bluetongue. Other causes include uremia (Fig. 7-6); foreign bodies, such as foxtail awns; the feline eosinophilic granuloma complex; and vitamin C deficiency in primates and guinea pigs (Fig. 7-7). Often the oral lesions must be evaluated in the context of the clinical signs, together with histopathologic findings and ancillary testing, to arrive at a definitive diagnosis. Additionally, the vesicular stomatitides can progress, secondary to abrasion, to the point that they cannot be distinguished from the ulcerative stomatitides.

**Fig. 7-3 Cutaneous vesicles, San Miguel sea lion virus infection, foreflippers, northern fur seal.** On the nonhaired portion of the foreflipper are vesicles both intact (*arrow*) and ruptured, caused by the infection of injured mucosal epithelial cells with San Miguel sea lion virus, a calicivirus. These vesicles will rupture with trauma, resulting in cutaneous erosion and ulceration. (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

**Fig. 7-4 Erosions and ulcers, bovine viral diarrhea virus infection, hard palate, cow.** Erosions and ulcers caused by this pestivirus are particularly evident here on the mucosal epithelial surface of the caudal hard palate. These lesions are characteristic of the ulcerative stomatitides, which, unlike the pox and parapox viruses, do not form vesicles. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 7-5 Erosions and ulcers, malignant catarrhal fever (MCF), hard palate, dental pad and buccal papillae, cow.** The erosions and ulcers (*red areas on mucosal surface*) are due to MCF virus, a herpes virus, but are characteristic of many ulcerative stomatitides. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-6 Uremic ulcers, hard palate, dog.** Ulcers present on the transverse palatine ridges and periodontal gingiva are secondary to vascular damage associated with increased concentrations of serum blood urea nitrogen and creatinine from kidney failure. Affected animals often have an ammoniacal or uremic odor to the breath. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.1.9

### PAPULAR STOMATITIDES

Parapoxviruses cause the papular stomatitides. The two major diseases in this category, bovine papular stomatitis and contagious ecthyma, are zoonotic. Bovine papular stomatitis is recognized by papules on the nares, muzzle, gingiva, buccal cavity, palate, and tongue (Fig. 7-8). Lesions also occur in the esophagus, rumen, and omasum. Microscopically, there is ballooning degeneration of the epithelial cells of the stratum spinosum. At a later stage, these cells may contain intracytoplasmic eosinophilic parapoxvirus inclusions (Fig. 7-9). Disease is more common in immunosuppressed animals, such as those persistently infected with bovine viral diarrheal virus. In human beings, the disease is called milker's nodules and is characterized by papules of the hands and arms.

**Fig. 7-7 Ulcerative gingivitis secondary to scurvy (vitamin C deficiency), gingiva, monkey.** There is a deep ulcer at the commissure of the mouth and smaller ulcers periodontally. Vitamin C deficiency in primates and guinea pigs can result in gingival erosions and ulcers, and even tooth loss. (Courtesy College of Veterinary Medicine, University of Illinois.)

**Fig. 7-8 Epithelial plaques, papular stomatitis, hard palate mucosa, calf.** Virus-induced (parapoxvirus) epithelial plaques and papules are present on the mucosal epithelium of the hard palate and adjacent gingiva (*arrows*). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

306

**Fig. 7-9 Ballooning degeneration, papular stomatitis, hard palate mucosa, cow.** There is ballooning degeneration of the epithelial cells of the stratum spinosum. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

307

## Pathologic Basis of Veterinary Disease, 4th Edition

Contagious ecthyma, or sore mouth, is a condition of sheep and goats characterized by macules, papules, vesicles, pustules, scabs, and scars in areas of skin abrasions, including the corners of the mouth (Fig. 7-10), mouth, udder, teats, coronary bands, and anus. Occasionally the mucosa of the esophagus and rumen also can be affected. Eosinophilic cytoplasmic inclusion bodies are visible at microscopic examination of lesions early in the course of disease. The condition in human beings is called orf.

7.2.1.10

### NECROTIZING STOMATITIDES

Necrotizing stomatitis occurs in cattle, sheep, and pigs. In cattle, it is sometimes referred to as calf diphtheria (Fig. 7-11). Necrotizing stomatitis is characterized by yellow-gray, round foci surrounded by a rim of hyperemic tissue in the oral cavity, larynx, pharynx, or tongue. Necrotizing stomatitis is the end stage of all other forms of stomatitis when they are complicated by infection with *Fusobacterium necrophorum*, a filamentous to rodlike to coccoid, gram-negative anaerobe. Bacterial toxins are responsible for the extensive lesions. Clinical signs include swollen cheeks, inappetence, pyrexia, and halitosis. Infection may become systemic if severe, resulting in lesions throughout the alimentary system and associated lymphoid tissue. Well-demarcated foci of coagulation necrosis typify the histologic appearance of necrotizing stomatitis. As might be expected in foci of inflammation, there is a circumferential rim of leukocytes and increased vascularity. Noma is a severe form of oral avascular necrosis associated with the presence of spirochetes and fusiform bacteria. Although rare, it is seen most commonly in primates, including humans, and dogs. It is characterized by severe necrotizing gingivitis, osteolysis, and sometimes death.

307

308

**Fig. 7-10 Contagious ecthyma, oral mucous membranes, lamb.** Note crusts around nose and lips. Multiple pustules and coalescing ruptured pustules covered by scabs are present on the skin. The parapoxvirus induces epithelial proliferation (acanthosis), followed by vesicle formation. These vesicles rupture and are quickly covered by scabs. Lesions develop at the sites of trauma, such as occur with a nursing kid, where damage to the superficial oral epithelium allows entry of the virus into skin. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 7-11 Necrotizing stomatitis, calf diphtheria, tongue, calf.** The dorsal surface of the tongue is ulcerated, and the ulcers are covered by a diphtheric membrane. Calf diphtheria is caused by infection with the bacterium *Fusobacterium necrophorum* secondary to abrasion and/or trauma to the mucosal epithelium of the oral cavity or larynx. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Ulcerative gingivitis (trench mouth), caused by anaerobic spirochetes, affects humans, some nonhuman primates, and rarely puppies. Similar to necrotizing stomatitis, ulcerative gingivitis is characterized by acute inflammation and necrosis, oral ulceration and pain, halitosis, a fragile oral mucosa, and ptyalism. In addition to *Fusobacterium* spp., *Borrelia vincentii* is causative. Debilitated animals and those with intercurrent infections are at increased risk for these secondary invaders. The morphologic diagnosis is an acute, necrotizing gingivitis. Unlike the case in necrotizing stomatitis, the causative agents are readily identified by tissue smears or by culture.

### 7.2.1.11 EOSINOPHILIC STOMATITIDES

Oral granulomas or ulcers (“rodent ulcers”) occur frequently in cats. Similar lesions occur sporadically in a variety of canine breeds. In cats, they are termed oral eosinophilic granulomas. Although the etiology of this

## Pathologic Basis of Veterinary Disease, 4th Edition

condition is unknown, the histologic appearance of lesions suggests an immune-mediated mechanism, possibly a hypersensitivity reaction to an unknown antigen. Antibodies to intercellular material can often be demonstrated in affected cats. In the majority of cases of both dogs and cats, an increase in circulating eosinophils is present.

In cats, lip lesions are commonly visible near the philtrum and may extend through the adjacent haired skin. Oral lesions may occur anywhere in the mouth including the gingiva, hard and soft palates, oral and nasal pharynx, tongue, and occasionally draining lymphoid tissues (Fig. 7-12). In dogs, eosinophilic granulomas typically are raised, fungating masses on the ventral and lateral lingual epithelium and palate. Collagenolysis (because collagen is acellular, it cannot undergo necrosis) is characteristically central in the lesion. The surrounding inflammatory tissue contains mixed inflammatory cells with increased numbers of eosinophils, mast cells, and multinucleated giant cells. Lesions grouped as the eosinophilic granuloma complex of cats include eosinophilic ulcers, linear granulomas, and eosinophilic plaques. The latter two lesions are strictly dermatologic and do not affect the oral cavity. No proven etiologic link has been established between these cutaneous conditions and oral eosinophilic granulomas. The cause of the canine lesions is unknown.

### 7.2.1.12 LYMPHOPLASMACYTIC STOMATITIS

Lymphoplasmacytic stomatitis is an idiopathic condition of the cat named on the basis of the histologic appearance of the lesions (Fig. 7-13). It is a chronic condition characterized by red, inflamed gums, fetid breath, and inappetence. The oral mucosa can be hyperplastic and ulcerated. Associations have been hypothesized between this condition and the presence of bacteria or calicivirus associated with feline leukemia virus (FeLV) and/or feline immunodeficiency virus infection.

Fig. 7-12 **Eosinophilic granuloma, skin, upper lip, cat.** Bilateral ulceration of the upper lip is present. The upper left lip is more extensively affected (arrow). (Courtesy Dr. Ann M. Hargis, *DermatoDiagnostics*.)

**Fig. 7-13 Lymphoplasmacytic stomatitis, gingiva, cat.** This chronic condition of cats is characterized by red, inflamed gums, fetid breath, and inappetence. The oral mucosa can also be hyperplastic and ulcerated. *Inset:* There is a florid infiltrate of mixed inflammatory cells, including many lymphocytes and plasma cells in the lamina propria beneath the epithelium. H&E stain. (**Figure**, Courtesy Dr. C. Patrick Ryan, Veterinary Public Health, Los Angeles Department of Health Services; and Noah's Arkive, College of Veterinary Medicine, University of Georgia. **Inset**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

308

### 7.2.1.13 CHRONIC ULCERATIVE PARADENTAL STOMATITIS

309

This condition of dogs, also known as ulcerative stomatitis and lymphocytic-plasmacytic stomatitis, is caused by apposition of “kissing ulcers” to dental plaque. The condition is painful with resultant inappetence and anorexia. Affected dogs drool and have halitosis. This condition occurs in older dogs of any breed, but Malteses and cavalier King Charles spaniels are particularly susceptible. The lymphocytic-plasmacytic lesions noted on histologic examination are suggestive of an inflammatory rather than infectious etiology. If untreated, bone resorption may occur.

### 7.2.1.14 HYPERPLASIA AND NEOPLASIA

In the dog, 70% of tumors of the alimentary system are in the oral cavity. These tumors run the gamut of biologic behavior from simple epithelial hyperplasia to malignant neoplasms with metastases to distant sites.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.1.14.1

### Hyperplastic Diseases

Gingival hyperplasia is a simple overgrowth of gum tissue. The hyperplasia can become so severe as to bury incisor teeth (Fig. 7-14). Gingival hyperplasia is most common in brachycephalic dog breeds and is present in 30% of boxer dogs older than 5 years.

Grossly, gingival hyperplasia can be indistinguishable from an epulis (Fig. 7-15). Epulis is a nonspecific term that designates a growth of the gingiva. The several kinds of epulides can only be distinguished by histopathologic examination. This distinction is not just an academic exercise because, although all epulides are considered benign, one form—acanthomatous epulis—invades bone and can be quite destructive. Fortunately, this type of epulis can be managed therapeutically. Whether the epulides represent fibrous and epithelial hyperplasia or benign neoplasms of tooth germ is controversial.

**Fig. 7-14 Gingival hyperplasia, gingiva, dog.** Hyperplastic gingiva has enveloped the lower incisor teeth. Dental calculus (*tartar, brown*) is also present on both upper and lower incisor and molar teeth. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-15 Fibromatous epulis, left mandible, molar teeth, dog.** This growth is an epulis (fibromatous type); however, epulides are often indistinguishable from gingival hyperplasia. Epulis is a term used to designate a growth of the gingiva that is firm, periodontal, and usually solitary, in contrast to gingival hyperplasia. This distinction is not just an academic exercise because, although all epulides are considered benign, one form, acanthomatous epulis, is locally invasive. It invades bone and can be quite destructive. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

7.2.1.14.2

### Neoplasia

Squamous cell carcinomas occur in the oral cavity, particularly in old cats, in which they account for 60% of oral neoplasms. They generally occur on the ventrolateral surface of the tongue and tonsils. Lingual squamous cell carcinomas occur more commonly in felids, and tonsillar squamous cell carcinomas are more common in canids. Although often appearing histologically aggressive, only a small percentage of

## Pathologic Basis of Veterinary Disease, 4th Edition

lingual neoplasms metastasize, most commonly to draining lymph nodes: the mandibular and medial retropharyngeal. Unfortunately, most tonsillar carcinomas do metastasize, often to distant sites.

Squamous cell carcinomas vary both in size and in gross appearance—from flat to proliferative (Fig. 7-16). These tumors are often quite aggressive locally, invading subjacent tissues. Some tumors contain more differentiated cells, keratin, often in whorls (keratin pearls) and visible desmosomes (intracellular bridges), whereas others are less well differentiated, with significant mitotic activity. In these latter cases, intracellular immunohistochemical markers for cytokeratin are useful in determining a definitive diagnosis. The amount of fibrous tissue within an individual tumor is variable. Some carcinomas induce a scirrhous response, whereas others have areas of necrosis caused by rapid tumor growth, “collision necrosis” of the tightly packed proliferating cells, and loss of contiguity with the blood supply.

309

310

**Fig. 7-16 Squamous cell carcinoma, palate, woodchuck.** A mass of proliferating neoplastic squamous epithelial cells has displaced and replaced the mucosa and underlying tissue of the left hard palate and gingiva. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Ninety percent of melanomas of the oral cavity of dogs are malignant. A breed predilection exists for Scottish terriers, Airedales, cocker spaniels, golden retrievers, Bedlington terriers, Duroc pigs, and others. Most melanomas contain copious intracellular pigment and are visibly black. Some melanomas without pigment, termed amelanotic melanomas, present a greater diagnostic challenge to both the clinician and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

pathologist (Fig. 7-17). Immunohistochemical staining for tyrosinase-related protein-2 is useful for identifying amelanotic tumors. Melanomas are composed of melanocytes and are of neural crest origin. Cellular morphology within melanomas varies from spindloid to epithelioid. Thus some neoplasms are histologically difficult to differentiate from squamous cell carcinomas, and others from fibrosarcomas.

Canine oral papillomatosis is a papovavirus-induced transmissible condition that usually occurs in animals younger than 1 year. The lesions usually regress spontaneously. Immunity is long-lasting. The lesions are papilliform or cauliflower-like and can become quite florid. They are generally white and friable and occur on the mouth, tongue, palate, larynx, and epiglottis. These oral tumors are usually multiple, white to gray, raised, and pedunculated with a keratinized surface and a stromal core. The epithelial cells comprising the lesion can be acanthotic, hyperplastic, and rest on a hyperplastic folded connective tissue stroma. The stratum spinosum is also hyperplastic and ballooned. Cytoplasmic inclusion bodies are sometimes present.

**Fig. 7-17 Amelanotic melanoma, mandibular symphysis, dog.** A proliferative, ulcerated nonpigmented mass is present on the oral mucosa at the mandibular symphysis and protrudes into the oral cavity, likely resulting in malocclusion. Incisor teeth have been lost. Note the absence of pigmentation (melanin) in this tumor. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Fibrosarcomas arise from the collagen-producing cells (fibroblasts) of the oral cavity. Fibrosarcomas are most common in the cat, accounting for 20% of oral neoplasia in that species.

### 7.2.2 TEETH\*

#### 7.2.2.1 INTRODUCTION

Teeth provide mechanical advantage for prehension, tearing and/or mastication of food. Among domestic animals, there are differences in the growth pattern and numbers of teeth. Hypsodont teeth, such as in the horse, continue to grow throughout life, and appropriate leveling of the occlusive surfaces (floating) may be necessary as the horse ages. Brachydont teeth, such as in carnivores, do not continue to grow after they are fully erupted. Most species of mammals have deciduous teeth that are replaced near maturity by permanent teeth. In many species, the approximate age of the animal may be obtained by eruption dates and examination of wear patterns and shape of the teeth.

\* Previous contributions to this section were authored by Dr. Richard Dubielzeg of the School of Veterinary Medicine, University of Wisconsin-Madison.

#### 7.2.2.2 STRUCTURE AND FUNCTION

Molar teeth in general are designed for grinding feedstuffs, whereas incisors in ruminants (mandibular only) are for cropping forage. Canine teeth are designed for tearing flesh. Brachydont teeth consist of a crown, which is the portion above the gingiva (the neck that is slightly constricted), and just below the gingiva are the roots, which are embedded in the bony socket (alveolus) of the jaw. Enamel covers the crown, cementum covers the roots, and both cover the dentin. Besides carnivores, the incisor (lower) teeth of ruminants and porcine teeth, except the canines of the boar, are brachydont.

Hypsodont teeth have an elongated body, but the neck and roots may form later in life. Cementum covers the tooth, and enamel is beneath the cementum. Beneath the enamel is the dentin. The cementum and enamel invaginate into the dentin, forming the infundibula. Enamel crests result from normal wear, with enamel being the hardest of the layers. The cheek teeth of ruminants and tusks of boars and the teeth of horses are hypsodont.

In simple-toothed animals, such as carnivores, the tooth root is not covered by enamel. Receding gum lines therefore expose the dentin, resulting in pain and invasion by bacteria. Domestic animal species seldom get caries, although buildup of plaque can result in gingival infections and tooth loss.

#### 7.2.2.3 MALOCCLUSIONS

Abnormal development and positioning of the teeth may affect dental function. Malocclusion refers to a failure of the upper and lower incisors to interdigitate properly. This feature is “normal” for some dogs, particularly the brachycephalic breeds. In the extreme, malocclusions can lead to difficulty in the prehension and mastication of food. Malocclusions are named according to the position of the mandible. Protrusion of the lower jaw is termed prognathia, whereas a short lower jaw with resultant protrusion of the upper jaw is termed brachygnathia and sometimes hypognathia (Fig. 7-18). Sometimes these terms are incorrectly used, referring to brachygnathia as superior prognathia and prognathia as superior brachygnathia.

**Fig. 7-18 Prognathia, head, horse.** The mandible is elongated compared with the maxilla. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Malocclusions result from abnormal jaw conformation or rarely from abnormal tooth eruption patterns. In some animals, such as rodents and rabbits, the teeth continue to grow throughout the animal's lifetime. If these animals are not provided with sufficient roughage in their diets, the teeth (both incisors and cheek teeth) overgrow and either “lock” the jaw or, because of a lack of occlusal grinding surfaces, prevent the animal from receiving proper nutrition (Fig. 7-19).

### 7.2.2.4

#### ANOMALIES OF TOOTH DEVELOPMENT

In simple-toothed animals, agenesis of a tooth or teeth occurs and is generally of no clinical significance. Supernumerary tooth development is less common than tooth agenesis and is similarly of little clinical significance. Some animals, such as elasmobranchs (sharks), continue to produce row upon row of teeth as the outer most rows are lost. Dental dysgenesis may be primarily due to dysplasias of the enamel-forming organ or secondary to trauma, infection and hyperthermia, toxicosis, or other metabolic irregularities.

Dentigerous cysts result from dental dysgenesis. Epithelial-lined, cystic structures in tissue, including the bone of the jaw, results. Dentigerous cysts develop from abnormal proliferation of the cell rests of Malassez. Although rare, dentigerous cysts are often painful, and although not usually neoplastic, they can destroy the jaw. Dentigerous cysts are epithelial-lined and may become impacted with keratin. Rudimentary, malformed teeth may be found within these cysts, and painful fistulas may develop, especially in horses. These draining tracts are seen most often rostral and ventral to the ear (ear tooth). Dentigerous cysts occur less frequently in otherwise normal, mature animals.

311

**Fig. 7-19 Overgrown teeth, head, guinea pig.** The incisors and molars are longer than normal and the tongue is entrapped by the lower molar teeth, which will lead to starvation unless properly corrected.  
(Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Segmental enamel hypoplasia occurs before eruption of the permanent teeth of dogs as a result of hyperthermia and viral infection. Most often, this is due to canine distemper virus infection. Enamel is fully formed when the teeth are erupted; therefore virus infection of ameloblasts must occur during enamel formation, before 6 months of age, if enamel hypoplasia is to occur. The epithelium of the enamel organ during virus infection is necrotic and disorganized. After clearing the virus infection, there is a return to normal structure and function of the enamel organ. Segmental enamel hypoplasia results because of the temporal lack of enamel formation (Fig. 7-20).

Chemicals, most notably tetracycline antibiotics, can cause permanent discoloration of otherwise normal teeth if such agents are present during the process of mineralization. Congenital porphyria, a defect in red blood cell production, may result in incorporation of porphyrins into dentin, resulting in pink discoloration of the teeth (pink tooth) (Fig. 7-21). Both tetracycline and porphyrins fluoresce under ultraviolet light, dramatically demonstrating these lesions.

Fluoride incorporation into the enamel and dentin occurs in fluoride toxicosis, particularly in cattle and sheep. A relationship exists in beef cattle between fluorosis and selenium supplementation, with

## Pathologic Basis of Veterinary Disease, 4th Edition

supplementation being protective in high fluoride areas. Excessive dietary concentrations of fluorine during odontogenesis (from 6 to 36 months of age) may result in incorporation of the fluoride in the enamel and dentin of the permanent teeth. The result is soft, chalky, discolored enamel, usually yellow, dark brown, or black (Fig. 7-22). Occlusal grinding of affected soft teeth against more normal enamel results in rapid dental wear. One wonders therefore about the cumulative effect of fluoride supplementation in municipal drinking water, vitamins with added fluoride, fluoride-supplemented toothpaste, fluoride treatment of teeth, reconstituted and bottled soft drinks made with fluoridated water, and so forth. It is difficult to calculate the total fluoride load ingested by individuals or what the effects of that fluoride supplementation may be.

312

313

**Fig. 7-20 Enamel hypoplasia, permanent incisor teeth, dog.** There is a lack of enamel formation with resultant discrete deep pits and exposure of the dentin (*light yellow to beige areas of the teeth*), the result of infection with canine distemper virus and necrosis of the ameloblasts during enamel formation. Permanent adult teeth (shown in illustration) are infected with virus before their eruption and while they are still within their sockets (dental alveoli). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-21 Pink tooth, congenital porphyria teeth, adult ox.** The teeth are discolored brown from the accumulation of porphyrins in the dentin. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 7-22 Fluorosis, cheek teeth, cow.** The enamel is chalky and weak, and the teeth are usually rapidly worn down. (Courtesy Dr. L. Krook, College of Veterinary Medicine, Cornell University.)

### 7.2.2.5

#### LESIONS CAUSED BY ATTRITION AND ABNORMAL WEAR

Loss of normal dental structure and function often results from rapid and irregular and/or abnormal wear of occlusal surfaces in many species of domestic animals. In those species with hypsodont teeth, attention to the dentition as the animal ages is often a major factor in overall body conditioning and health (Fig. 7-23). Aggressive treatment of occlusal surface irregularity by filing of high points in the dental arcade (floating) can notably prolong an animal's life. Rock chewing or other compulsive oral behaviors in dogs may result in accelerated dental wear. In all species, exposure of dentin or the pulp canal may lead to dental infection with serious consequences.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.2.6 FELINE EXTERNAL RESORPTIVE NECK LESIONS

Cats suffering from feline external resorptive neck lesions often have pain upon chewing that may be reflected by inappetence and/or abnormal masticatory movements. External neck resorption of the teeth of otherwise dentally normal cats is caused by odontoclastic resorption of dental tissue, particularly in the neck area or root of the tooth. Cementum or osteoid ingrowths partially or completely line the resorptive cavity. The resultant cavity may attract bacterial plaque, resulting in intense inflammation and osteoclastic resorption of dental tissue. The primary cause of this condition is not known.

**Fig. 7-23 Dental attrition, molar teeth, antelope.** Age-associated dental wear results in improper mastication of feedstuffs and malnutrition. This condition occurs most commonly in horses and is referred to as “step-mouth.” (Courtesy College of Veterinary Medicine, University of Tennessee.)

### 7.2.2.7 INFUNDIBULAR IMPACTION

Impaction of the infundibulum, infundibular necrosis or infundibular caries, may cause serious dental disease in ruminants and more rarely in horses. Incomplete infundibular cementum formation before tooth eruption likely predisposes to infundibular impaction. The pathogenic mechanism is comparable to dental caries in simple-toothed animals. Feed material is ground into the infundibulum, where bacteria metabolize it to form acid, which causes demineralization. Bacterial enzymes digest the organic matrix of enamel and dentin. As a result of this destruction, the pulp cavity becomes infected, resulting in pulpitis and endodontitis. Dental abscesses and fistulous tracks may develop. The inflamed infundibular cavities often continue to become impacted with feed, creating a vicious cycle.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.2.8

### PERIODONTAL DISEASE

Bacterial films resident on the tooth surface and the acids and enzymes they produce may damage their enamel substrate (cavities) and also destroy the subjacent gingival tissue and periodontal ligament (periodontal disease). More than 200 species of bacteria and fungi have been associated with dental plaque (a film of an organic matrix, food particles and bacteria on the tooth surface). This plaque often becomes mineralized (tartar or dental calculus). The mineralized material contributes to atrophy and inflammation of the gingival epithelium and supporting stroma by acting as a nidus for additional plaque accumulation.

The initial site for destructive inflammation is in the gingival crevice-forming pockets. With time, this inflammation spreads distally along the tooth, resulting in gingival-epithelial attachment only on the root of the tooth, deep in the alveolar socket. Progression of inflammation destroys the connective tissue of the periodontal ligament, resulting in loosening of the tooth. Alveolar osteomyelitis and pulpitis can form apical abscesses, bacteremic spread of inflammation, significant oral pain, reluctance to masticate, and halitosis. Periodontal disease is common in carnivores and humans. Mildly abrasive diets and brushing of the teeth of pet carnivores, combined with regular dental examination, is preventative in carnivores as it is in human beings.

313

314

7.2.2.9

### DENTAL NEOPLASIA

Proliferative, cystic or neoplastic diseases of the dental arcade can originate from cell rests that form from the dental lamina or the enamel organ (the cell rests of Malassez). Dental neoplasms usually arise in proximity to the teeth, either deeply in the jaw or from the surface epithelium. There is a relatively precise method of naming dental neoplasms based on the tissue or cell of origin and the extent of differentiation and odontogenesis present within the neoplastic tissue. The histologic appearance of these neoplasms is complex; pathologists with considerable experience in differentiating these uncommon neoplasms should be consulted when a precise diagnosis is indicated.

Odontomas are hamartomas originating in the enamel organ, usually of puppies and foals ([Fig. 7-24](#)). They usually contain well-recognizable dentin and enamel as well as ameloblasts, odontoblasts, and dental pulp.

Ameloblastoma is a term applied to epithelial neoplasms of enamel organ origin. Several subtypes can be distinguished histologically. They are ameloblastic fibroma, ameloblastic odontoma, calcifying epithelial odontogenic tumor, peripheral odontogenic fibroma, and other rare tooth neoplasms.

**Fig. 7-24 Odontoma, incisor teeth, cow.** This is a hamartoma (a benign tumorlike nodule) of the enamel organ and in this case has expanded bilaterally on the rostral mandibles. There is extensive hemorrhagic ulceration over the tumor. Diagnosis can be confirmed by radiographic and histopathologic examination. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Ameloblastoma appears randomly in the dental arcade, usually in adult dogs. They are often osteolytic and thus are locally invasive. Histologic examination by an expert is often necessary to distinguish ameloblastoma from acanthomatous epulis and squamous cell carcinoma.

### 7.2.3 TONSILS

#### 7.2.3.1 STRUCTURE AND FUNCTION

The palatine tonsils are pharyngeal lymphoid structures covered by stratified squamous epithelium. Their function is uncertain, although it is likely they serve in lymphocyte production and antibody formation. In carnivores, they are found in crypts or recesses at the dorsolateral aspect of the caudal oropharynx. In pigs, they are flat and recognized by tiny pores in the surface epithelium of the caudal soft palate. Equids, ruminants, and pigs have lingual tonsils in addition to palatine tonsils.

#### 7.2.3.2 PORTALS OF ENTRY

Tonsils do not possess afferent lymphatics and do not serve as lymph filters. Therefore only primary (or direct) or hematogenous infections occur (tonsillitis) (Fig. 7-25), and primary neoplasms of either the lymphoid (lymphosarcoma) (Fig. 7-26) or epithelial (squamous cell carcinoma) (Fig. 7-27) components. In many viremias of mammals, such as pseudorabies of pigs, virus may be isolated from the tonsils.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.4 SALIVARY GLANDS

#### 7.2.4.1 INTRODUCTION

Salivary glands are found in a variety of locations in the head and neck regions. They arise from oral ectoderm. In all species the major salivary glands include the parotid, mandibular, and sublingual. Carnivores have a zygomatic gland as well. Minor salivary glands include buccal, labial, lingual, palatine, and others similarly named by location.

#### 7.2.4.2 STRUCTURE AND FUNCTION

Most salivary glands are discrete aggregates of compound tubuloalveolar tissue. Saliva is a mixture of serous and mucoid secretions. Saliva lubricates the mouth and esophagus and moistens ingesta. Saliva also dissolves water-soluble components of food so the taste buds can function. The mucus in saliva binds to masticated food and creates a bolus that is more easily swallowed. Salivary mucus also coats the epithelium of the mouth, preventing mechanical damage to the tissue. Saliva, through its flushing action, reduces bacterial populations. Saliva contains a lysozyme that lyses bacteria. Carbohydrate digestion begins in the oral cavity as a result of the presence of  $\alpha$ -amylase, which changes starch into maltose. There are very small quantities of this enzyme in carnivores and cattle. Saliva also is an effective buffer, especially in ruminants, whose forestomach have no glands. In carnivores, evaporation of saliva is a major mechanism of thermoregulation.

314

315

**Fig. 7-25 Necrotizing tonsillitis, tonsils, dog.** The palatine tonsils are enlarged and discolored. The left tonsil is covered by a diphtheritic membrane, and the right tonsil is extensively ulcerated. Because there are no afferent lymphatics to the tonsils, infection is either primary (by direct spread) or hematogenous. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-26 **Lymphoma (lymphosarcoma), tonsil, dog.** Proliferation of malignant lymphocytes has expanded the tonsils so that they now protrude beyond their crypts. (*Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 7-27 Squamous cell carcinoma, tonsil, cat.** The right tonsil has been replaced by a large expansile neoplasm. The left tonsil is normal and remains in its crypt. (Courtesy Dr. R. Storts, College of Veterinary Medicine, Texas A&M University.)

### 7.2.4.3 PORTAL OF ENTRY

Salivary glands are generally affected by blood-borne pathogens, direct penetration by foreign objects, obstruction of the excretory ducts, or bite wounds. In humans, ascending infections from the salivary ducts occur. There is no reason to suspect that ascending infections do not occur in other mammals as well. The serous portions of the salivary gland are radiosensitive.

### 7.2.4.4 INFLAMMATORY DISEASES

Sialoadenitis or inflammation of a salivary gland is relatively rare in veterinary medicine. Although diagnosis of systemic diseases is not made by examining the salivary gland, rabies and canine distemper are two very important diseases that cause inflammation of the salivary glands. Saliva is a particularly important medium of spread, in bite wounds, of the rhabdovirus that causes rabies. In the rat, a coronavirus termed

## Pathologic Basis of Veterinary Disease, 4th Edition

sialodacryoadenitis virus is responsible for inflammation of the salivary gland and some adnexal ocular glands. *Salmonella typhisuis* has caused parotid sialoadenitis in pigs.

315

Gross lesions of sialoadenitis are subtle and include swelling and edema. Sialoadenitis can be accompanied by pain on palpation. Abscesses occasionally occur and are especially noticeable when they occur in the retrobulbar zygomatic gland where they may cause ocular protrusion (proptosis).

316

7.2.4.5

### MISCELLANEOUS DISEASES OR CONDITIONS

Changes in the salivary glands are uncommon in domestic animal species. A ranula is a cystic saliva-filled distention of the duct of the sublingual or submaxillary salivary gland that occurs on the floor of the mouth alongside the tongue (Fig. 7-28). It is thus epithelial lined. The cause is generally unknown, although some cases are due to sialoliths. A salivary mucocele, in contrast, is a pseudocyst not lined by epithelium but filled with saliva. The cause of this lesion is also unknown, but it may occur secondary to traumatic rupture of the duct of a sublingual salivary gland with resultant leakage and encapsulation of saliva by reactive connective tissue.

Sialoliths are rare in domestic animal species. When they do occur, they are considered to be caused by inflammation of the salivary gland with sloughed cells or inflammatory exudate forming a nidus for mineral accretion (Fig. 7-29). Thus they are one cause of ranula formation.

7.2.4.6

### NEOPLASIA

Salivary gland neoplasms, both benign and malignant, are uncommon but occur in all species (Fig. 7-30). They are composed of glandular or ductular elements or a combination of epithelial and mesenchymal components similar to those in mixed mammary neoplasms. A grossly appearing similar condition, salivary gland infarction, occurs infrequently in cats and rarely in dogs. The cause of the infarction is unknown. The gross appearance of firmness and swelling of an infarcted gland must be distinguished microscopically from neoplasia (Fig. 7-31). In salivary gland infarction, there are discrete foci of parenchymal necrosis with peripheral hemorrhage and inflammatory cells. Regeneration of the gland can be mistaken for neoplasia unless one is familiar with the former condition.

**Fig. 7-28 Ranula, mandibular salivary duct, dog.** This is a cystic distention of the left mandibular salivary duct along the ventral-lateral aspect of the tongue. (Courtesy Dr. P. Stromberg, College of Veterinary Medicine, The Ohio State University.)

(**Figure** and **Inset**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## 7.2.5 TONGUE

### 7.2.5.1 INTRODUCTION

The tongue is a muscular organ covered by stratified epithelium and is functionally connected to the esophagus via the epiglottis.

### 7.2.5.2 STRUCTURE AND FUNCTION

The tongue is necessary for prehension, mastication, and swallowing of feedstuffs and water. The epithelial covering of the tongue is stratified squamous dorsally with various degrees of keratinization, but ventrally the epithelium is not keratinized and attaches the tongue to the floor of the oral cavity by a frenulum. Keratinized papillae are most prominent in ruminants and cats. There are various types of papillae, some with secondary lamellas. Vallate papillae, for example, are on the dorsal surface of the tongue near its root and are flat structures completely surrounded by a cleft. Some surface macroscopic papillae contain taste buds. The tongue is a highly vascular (functioning in heat loss in many animals, especially carnivores that have no sweat glands) and sensitive organ containing a variety of serous and mucus glands and sensory cells (taste buds). The muscular part of the tongue is striated in randomly arranged bundles. A cordlike structure enclosed in dense collagen extending lengthwise near the ventral central surface of the tongue of carnivores is called the lyssa. Porcine and equid tongues have a similar structure. The lyssa appears to be a structure without a function. Historically the lyssa was removed as “prevention” for rabies. Lyssa bodies are

## Pathologic Basis of Veterinary Disease, 4th Edition

synonymous with Negri bodies, and rabies used to be called lyssa. Adipose tissue becomes more abundant in the caudal part of the tongue in most species.

7.2.5.3

### DEVELOPMENTAL ANOMALIES

Congenital diseases of the tongue include epithelial defects such as fissures, epitheliogenesis imperfecta, macroglossia and microglossia, bifid tongue, and hair growing from the tongue (Fig. 7-32). Lethal glossopharyngeal defect, or bird tongue of dogs, is characterized by a pointed tongue that cannot wrap around a nipple and create the negative pressure required for nursing. Without intervention, starvation results. Ventral ankyloglossia, fusion of the tongue to the floor of the oral cavity, has been reported in related Anatolian shepherd dogs. The cause of these congenital lesions is not known, but they sometimes occur in association with other defects. As in the case of other congenital defects, ingestion of teratogenic substances by the dam during gestation is an etiologic possibility, as is mutation of T-box genes.

7.2.5.4

### SYSTEMIC DISEASE: PRIMARY INVOLVEMENT OF THE TONGUE

Disease agents that principally target the tongue are relatively rare. The exception to this rule is *Actinobacillus lignieresii*, a gram-negative bacillus that is a normal inhabitant of the oral cavity. *Actinobacillus lignieresii* is an opportunistic invader of damaged lingual tissue, principally in bovids and occasionally in equids and small ruminants. The granulomas resulting from infection contain centrally located actinobacilli rimmed by radiating amorphous eosinophilic, clublike structures composed of immunoglobulin molecules from lesion plasmacytes (Fig. 7-33). Mixed mononuclear inflammatory cells, including multinucleated Langhans' giant cells, often surround these foci (Splendore-Hoeppli phenomenon) and may be present in regional lymph nodes. The amount of fibrous tissue present is dependent on the duration of the inflammation. The resulting lingual disease is called wooden tongue; the name is derived from the swelling, inflammation, and fibrosis that causes increased firmness of the tongue and linguomegaly (Fig. 7-34). Horses are rarely affected by *Actinobacillus lignieresii* infections, but they are manifested as cutaneous or lymph node abscesses, mastitis, and occasional glossitis.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.5.5

### SYSTEMIC DISEASE: SECONDARY INVOLVEMENT OF THE TONGUE

Thrush is a *Candida albicans* (yeast) infection of intact mucous membranes of the tongue and esophagus (Fig. 7-35). It occurs principally in ungulates but has also been seen in carnivores. Thrush is not a primary disease but often indicates an underlying debility, particularly in young animals. This infection presents as a gray-green pseudomembrane that is easily scraped off the intact underlying mucosal surface (Fig. 7-36). It occurs as a result of antibiotic treatment that kills normal flora, increased serum glucose concentrations as a result of diabetes mellitus, a high-sugar diet, or intravenous glucose therapy. The availability of iron is a limiting factor for the indigenous bacteria, which compete with yeast for mucosal colonization. Immunodeficiency states also contribute to the development of thrush. All of these scenarios provide tissue conditions suitable for the proliferation of yeast forms. Rarely, systemic infection may result. Factors predisposing to systemic infections include multiple antibiotic usage, indwelling catheters, and endotracheal tubes.

318

319

**Fig. 7-36 Thrush, tongue, foal.** A pseudomembrane of hyphae of *Candida* is present on the dorsal surface. It has been scraped off the rostral end of the tongue (*top*) to reveal normal mucosa beneath the fungal mat. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Often, lingual lesions are manifestations of systemic diseases, such as BVD, foot-and-mouth disease, multisystemic amyloidosis, and uremia ([Fig. 7-37](#)). Some of these diseases are discussed in more detail elsewhere in other chapters of this book.

### 7.2.5.6

#### HYPERPLASTIC AND NEOPLASTIC CONDITIONS

Epithelial hyperplasia of the lateral edges of the tongue is common in piglets before nursing, when the fringelike epithelium is rubbed off ([Fig. 7-38](#)).

Lingual (glossal) neoplasms are rare but, when they occur, are generally of epithelial origin. Squamous cell carcinomas are most common ([Fig. 7-39](#)), but papillomas ([Fig. 7-40](#)), rhabdomyomas, rhabdomyosarcomas, fibrosarcomas, melanomas, and granular cell tumors have all been reported in domestic animals.

**Fig. 7-37 Ulcerative glossitis, uremia (uremic glossitis), tongue, horse.**

**Fig. 7-38 Lingual epithelial hyperplasia, tongue, neonatal pig.**

The lateral surfaces of the tongue are covered by a hyperplastic epithelial fringe. This fringe is normal at birth and will be lost through mechanical trauma to the fringe during nursing. (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.5.7 PARASITES

Parasites of the tongue are uncommon, with the exception of those that reside in muscles, such as *Sarcocystis* spp. and *Trichinella spiralis* in pigs and occasionally in carnivorous wildlife such as polar bears. *Gongylonema* spp. can be present in the mucosa of pigs and ruminants and are of no clinical significance.

### 7.2.6 ESOPHAGUS

#### 7.2.6.1 INTRODUCTION

Under normal circumstances, the esophageal lumen is a potential space. The wall collapses when the esophagus is not transporting ingesta.

319

320

**Fig. 7-39 Squamous cell carcinoma, tongue (dorsal surface), dog.** Note the proliferative, ulcerated, and hemorrhagic neoplasm growing transversely across the surface of the tongue. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-40 Papillomas, tongue (ventral surface), cow.** Papillomas, often caused by bovine papillomavirus, are present on the ventral surface of the tongue. The virus infects traumatized mucosal epithelial cells and induces epithelial cell proliferation. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 7.2.6.2

#### STRUCTURE AND FUNCTION

The esophagus extends from the distal end of the oropharynx, passes through the mediastinum, and ends at the cardia of the stomach at the diaphragmatic hiatus. Protrusion of the stomach through the diaphragm into the thoracic cavity at this location is termed a hiatal hernia. The esophagus is lined by nonkeratinizing stratified squamous epithelium in carnivores and is keratinized in pigs, horses, and ruminants. Keratinization is greatest in ruminants, less in horses, and least in pigs. Longitudinal and oblique mucosal folds are present to varying degrees.

The tunica muscularis is completely striated in ruminants and dogs. In the horse, the distal third of the esophagus contains smooth muscle. The pig is similar to the horse, except that the middle third of the esophagus contains a mixture of smooth and striated muscle. In the cat, opossum, and primates, the distal two thirds of the esophagus is composed of smooth muscle. The smooth muscle is arranged as an inner circular layer and an outer longitudinal layer.

Mixed mucinous glands are present in the tunica submucosa of pigs and dogs. In pigs the glands are most abundant in the cranial half of the esophagus, and in dogs they are present throughout. Glands are present in cats, horses, and ruminants only at the junction of the esophagus and pharynx.

It is important to remember that unlike the rest of the tubular digestive tract, the esophagus is unique in that it lacks a serosa in all but the abdominal portion. This means that sutures are not likely to seal an incision. Combine this with the strong muscular contractions that characterize this organ and it is easy to understand

## Pathologic Basis of Veterinary Disease, 4th Edition

why esophageal surgery is not often performed and is even less often successful. For the same anatomic reason, perforating foreign bodies of the esophagus do not seal themselves off.

7.2.6.3

### PORTALS OF ENTRY

All materials passed from the oral cavity traverse through the esophagus to the stomach or rumen, including caustic chemicals. Penetration or obstruction by foreign objects is the most common portal of entry (Fig. 7-41). Some parasites spend part or all of their life cycles in the esophagus. Iatrogenic puncture of the esophagus is a not uncommon sequela to passage of stomach tubes. Gastric reflux is an additional portal of entry into the esophagus.

7.2.6.4

### DEVELOPMENTAL ANOMALIES

Esophageal motility disorders are termed achalasia. In this condition, the sequential contractility of the esophagus is defective and the lower sphincter fails to function properly. Achalasia results in difficulty in swallowing and may be associated with regurgitation and weight loss.

320

321

**Fig. 7-41 Foreign body with necrosis, esophagus, dog.** A ham bone lodged in this dog's esophagus dorsal to the base of the heart has caused esophageal dilation and pressure necrosis of the esophageal mucosa. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

Cricopharyngeal achalasia is a congenital, possibly neurogenic, disorder of the upper esophageal (cricopharyngeal) sphincter. It occurs in young, small breed dogs, particularly terriers, cocker spaniels, and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

miniature poodles. Postweaning dysphagia and regurgitation after a meal of solid food is characteristic of this functional disorder. Liquids are generally swallowed without incidence. Gagging or choking behavior of the patient after swallowing is a good indicator, in the appropriately aged dog, of this condition.

Acquired canine achalasia is extremely uncommon. In this condition, there is often a visible abnormality of the musculature of deglutition (cricopharyngeus). There does not appear to be a characteristic change in the affected musculature. Esophageal myotomy is therapeutic for this idiopathic condition.

### 7.2.6.5

#### MEGAESOPHAGUS

Megaesophagus or esophageal ectasia is dilation of the esophagus because of insufficient or uncoordinated peristalsis in the mid and cervical esophagus. It has been described in dogs, cats, cows, ferrets, horses, and new world camelids. Causes include motility problems related to innervation or denervation disorders and to partial physical obstructions and stenosis, secondary to inflammatory diseases of esophageal musculature or persistence of the right aortic arch. Many cases are idiopathic.

Congenital megaesophagus is due to partial blockage of the lumen of the esophagus by a persistent right fourth aortic arch. Because of the persistence of the arch, a vascular ring forms around the esophagus and trachea, preventing full dilation of the esophagus. The ring is formed by the aorta, pulmonary artery, and ductus arteriosus. This form of megaesophagus is unique in that the esophageal obstruction, and thus dilation, occurs cranial to the heart because of the location of the obstructing vascular ring ([Fig. 7-42](#); also see [Fig. 10-23](#)). Persistent right aortic arch is likely hereditary in German shepherds, Irish setters, and greyhounds. All other forms of megaesophagus result in dilation cranial to the stomach.

Congenital megaesophagus also occurs as an idiopathic denervation of the esophagus, most notably in Great Danes, Irish setters, miniature schnauzers, Labrador retrievers, wire hair fox terriers, Shar-Peis, Newfoundlands, and Siamese cats. Myasthenia gravis (see later discussion) may be of genetic origin in a small number of cases.

Acquired megaesophagus or esophageal achalasia is the result of failure of relaxation of the distal esophageal or cardiac sphincter of the stomach in human beings. The obstruction, and thus dilation, occurs cranial to the stomach ([Fig. 7-43](#)). Although the gross appearance of acquired megaesophagus in animals is similar to that of human beings, the cause of the condition in animals does not involve the cardiac sphincter. Causes are idiopathic or secondary to polymyositis (inflammation of the esophageal muscle), myasthenia gravis (an autoimmune disease directed against acetylcholine receptors of the neuromuscular junction), hypothyroidism (which can result in muscle atrophy and denervation disease), congenital myopathy, lead and thallium poisoning (via effect on innervation), peripheral neuropathies, esophagitis, and recurrent gastric dilation. Increased risk is seen in German shepherds, golden retrievers, and Irish setters.

Fig. 7-42 **Megaesophagus from a persistent right aortic arch, esophagus, dog.** Dilation of the esophagus cranial to the heart is the result of failure of the right fourth aortic arch to regress during embryonic life (vascular ring abnormality). (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

321

Fig. 7-43 **Megaesophagus, thoracic esophagus, dog.** A notably dilated thoracic esophagus cranial to the diaphragm has displaced the right lung caudally and ventrally. This form of megaesophagus is often attributable to an abnormality (mass, foreign body, innervation disorder) affecting the cardiac sphincter. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

322

Megaesophagus is recognized clinically by regurgitation after ingestion of solid food. Thus congenital megaesophagus is often recognized at weaning. Often animals are thin and may have aspiration pneumonia. Radiographically, in megaesophagus, the esophagus is dilated and retains radiopaque dyes (Fig. 7-44).

## Pathologic Basis of Veterinary Disease, 4th Edition

Dilation may vary from diffuse to locally extensive depending on its cause. Putrid ingesta are sometimes found in the dilated, atonic portions of the esophagus. Although degenerated nerve fibers are occasionally found within vagus nerves, megaesophagus can occur without histologic lesions.

7.2.6.6

### ESOPHAGEAL PARASITES

With notable exceptions, parasitic diseases of the esophagus are generally of no clinical importance. The more common parasites of the esophagus are *Gongylonema* spp., which affect ruminants, pigs, horses, primates, and occasionally rodents. These nematodes reside in the mucosa, and are characteristically thin, red, and serpentine. They can be 10 to 15 cm in length and are easily visible (Fig. 7-45). The intermediate hosts are cockroaches and dung beetles.

*Gasterophilus* spp. occur in equids. These fly larvae have interesting life cycles because their eggs are laid on the skin in varying locations. The warmth and moisture from licking activates them. The larvae burrow into the oral mucosa, molt, and then migrate down the esophagus. They occur both in the distal esophagus and stomach where they attach to the mucosa via oral hooks. They eventually detach, leaving craters at the site of attachment, and pass in the feces.

**Fig. 7-44 Megaesophagus, thoracic radiograph, dog.** Swallowed radiopaque imaging agent (barium sulfate) demonstrates dilation of the esophagus cranial to the diaphragm. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-45 **Gongylonemiasis, esophagus, cow.** The serpentine intramucosal nematodes are characteristic of *Gongylonema*, a nematode of the superfamily Spiruroidea. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

*Hypoderma lineatum* is the larvae of the warble fly of ruminants. These parasites eventually migrate to the esophageal adventitia and then to the subcutaneous tissue of the back.

Probably the most pathogenic of the esophageal parasites is *Spirocerca lupi* of canids. These nematodes reach the esophageal submucosa after migrating from the stomach through the aortic wall. A passage forms between the esophageal lumen and the granuloma containing the parasite, allowing discharge of ova into the lumen of the alimentary system and eventually into the feces. Clinical sequelae of infestation include dysphagia, aortic aneurysms, hemothorax, and rarely esophageal fibrosarcomas or osteosarcomas (Fig. 7-46). Spondylosis deformans develops occasionally in the vertebral bodies of chronically affected canids adjacent to the aortic granulomas. *Spirocerca lupi* infestations occur in warmer climates. The intermediate hosts are dung beetles, and the paratenic hosts are chickens, reptiles, and rodents.

322

323

7.2.6.7

### MISCELLANEOUS ESOPHAGEAL LESIONS AND CONDITIONS

Idiopathic muscular hypertrophy of the distal esophagus is a peculiar lesion in horses and pigs that can be quite spectacular at necropsy (Fig. 7-47), but usually it is of no clinical significance. The esophageal musculature can be several centimeters thick, and the lesion can extend along the distal quarter of the esophagus. Rarely this condition plays a role in esophageal impaction. Similarly, dilation of the esophageal glands of aged dogs can be a spectacular gross lesion of no clinical consequence. It is therefore important to

## Pathologic Basis of Veterinary Disease, 4th Edition

---

carefully evaluate these lesions either at necropsy or during fiberoptic viewing in the live animal to determine whether what appear to be erosions and ulcers are rather mucosal elevations filled with mucus. Because the lesions are subepithelial, the overlying mucosa is smooth and shiny. Dilated esophageal glands vary in number and location but are generally only a few millimeters in diameter (Fig. 7-48). They are most numerous in the distal esophagus.

**Fig. 7-46 Fibrosarcoma, esophagus, dog. *Spirocerca lupi*** (longitudinal section) (*arrows*) is present in the esophageal submucosa deep to the fibrosarcoma, which it has induced (*arrowheads*). H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-47 Muscular hypertrophy, distal esophagus, horse.** Longitudinal (*left*) and transverse (*right*) sections of the esophagus demonstrate the marked increase in the thickness of the smooth muscle in the tunica muscularis of the distal esophagus. (*Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.*)

**Fig. 7-48 Cystic esophageal glands, distal esophagus, dog.** Multiple white mucosal cysts are present in the esophageal glands of the mucosa and submucosa. These cysts are common and insignificant findings in aged dogs. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Esophageal erosions and ulcers are relatively common and have a variety of causes. One of the more common causes of esophageal erosions and ulcers is reflux of stomach acid. This reflux of gastric acids causes chemical burning of the lower esophagus and is commonly called acid reflux esophagitis (Fig. 7-49) or heartburn in human beings. Other causes of esophageal ulcers include improper use of stomach tubes, which cause linear scraping on the crests of the longitudinal folds of the esophageal mucosa (Fig. 7-50), and infectious diseases, such as BVD (Fig. 7-51), which cause mucosal injury in other locations as well.

323

324

**Fig. 7-49 Acid reflux esophagitis, esophagus, horse.** The dark red streaks on the surface of the esophagus are areas of epithelial loss secondary to gastric acid reflux. The white streaks and vertically linear areas on the surface of the esophagus are areas of unaffected and likely hyperplastic mucosal epithelium. As would be expected, erosions are most severe on the esophageal mucosa adjacent to the cardia and extend rostrally. This distribution is diagnostic of acid reflux esophagitis. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Leukoplakia of the esophagus and stomach is characterized by discrete, flat, white mucosal elevations (epithelial plaques) of no clinical significance and of unknown cause. They are sometimes mistaken for thrush lesions or neoplasia. Unlike thrush lesions, they do not scrape off easily, and their regularity, number, and location distinguish them from neoplasms. Histologically the stratum germinativum and prickly cell layers are notably thickened, and the surface cells have pyknotic nuclei and some parakeratosis. In human beings, about 5% of these lesions become cancerous. They are present in the oral cavity and esophagus and are believed related to chronic irritation most often associated with smoking or chewing tobacco. Alcohol consumption and restorative dental amalgams may also predispose to leukoplakia.

### 7.2.6.8

#### CHOKES

Choke is a clinical term referring to esophageal obstruction subsequent to stenoses or blockage. Choke most often occurs in those anatomic locations where the esophagus cannot fully expand. These locations are dorsal to the larynx and at the thoracic inlet, base of the heart, and the diaphragmatic hiatus. Choke occurs most frequently as a result of ingestion of large foreign bodies such as potatoes, apples, bones (Fig. 7-52), corn cobs (Fig. 7-53), or medicaments such as large gelatin-filled capsules or tablets (dry boluses). If these bodies are lodged against the epithelium for longer than 2 days, the interaction often results in circumferential pressure necrosis of the esophageal mucosa (Fig. 7-54), which forms strictures during healing. These strictures then can cause reflex regurgitation after ingestion of food.

324

325

**Fig. 7-50 Trauma-induced esophageal ulceration, esophagus, horse.** These red linear ulcers are the result of abrasion from improper stomach tubing, either from an overly large diameter tube, from a too-vigorous insertion, or from a tube with a roughened edge. *(Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)*

**Fig. 7-51 Ulcerative esophagitis, bovine viral diarrhea, esophagus, cow.**  
Note the multiple variably sized (millimeter range) and variably shaped esophageal mucosal ulcers caused by the pestivirus of bovine viral diarrhea. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-52 Ulcers and perforation, foreign body, esophagus, dog.** The esophagus has been perforated by an ingested chicken bone. Note that the end of the bone opposite the perforation site has caused a deep ulcer (*arrow*). There are also several chronic ulcers caudal to the perforation, presumably from abrasion by other bones as they moved down the esophagus. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

In older horses, poor dentition causes feed to be incompletely masticated, resulting in impaction in the esophagus. Neoplastic or inflammatory lesions of the esophagus or periesophageal tissues also cause obstruction. Persistence of the right aortic arch has already been discussed as a cause of esophageal stenosis and megaesophagus.

### 7.2.6.9

#### NEOPLASIA

Neoplasms of the esophagus are rare. Bracken fern (*Pteridium aquilinum*) consumption has been associated with squamous cell carcinomas in felids and equids. The clinical signs are similar to those of other causes of esophageal blockage and include dysphagia, regurgitation, weight loss, and dilation of the esophagus proximal to the mass. Tumors of the esophagus are occasionally palpable, but are most often intraluminal rather than mural. Epithelial tumors include papillomas (Fig. 7-55) and squamous cell carcinomas. The later have wide metastatic potential. Smooth muscle tumors of the esophagus are also rare, but may result in similar clinical signs whether benign or malignant (Fig. 7-56). Esophageal fibrosarcomas of dogs are often associated with *Spirocerca lupi* infestation. Esophageal lymphosarcoma occurs sporadically in most species (Fig. 7-57).

325

326

**Fig. 7-55 Papillomatosis, bovine papilloma virus, esophagus, bull.**

Multiple papillomas, characteristic of this viral-induced disease, occur following trauma to the esophageal mucosa and infection of mucosal epithelial cells. Oral papillomas may be present concurrently. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

### 7.2.7 RUMEN, RETICULUM, AND OMASUM

#### 7.2.7.1 INTRODUCTION

The three compartments of the ruminant forestomach are the reticulum, rumen, and omasum. The forestomach is subdivided by folds and compartments. Normal forestomach motility, and thus innervation, is critical in maintaining digestive homeostasis. The forestomach is aglandular. The resident flora and fauna are responsible for digestion and fermentation. In general, the rumen is a large fermentation vat where microorganisms break down ingesta by mechanical and chemical action into short chain fatty acids, which

## Pathologic Basis of Veterinary Disease, 4th Edition

are directly absorbed across the epithelial lining into the blood and constitute more than half of the absorbable energy. The reticulum and omasum act mechanically to further reduce the ingesta to fine particles.

**Fig. 7-56 Leiomyoma, esophagus, dog.** A mass consisting of submucosal proliferation of smooth muscle cells bulges into the distal esophageal lumen causing obstruction. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-57 Lymphoma (lymphosarcoma), esophagus, dog.** Masses of submucosal proliferating malignant lymphocytes bulge into the esophageal lumen, causing partial obstruction. Note that the mucosal epithelium is intact (smooth and shiny). (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

The rumen has small papillae that vary by diet up to 1.5 cm in length. Papillae are longer with high roughage diets and shorter when more concentrates are in the ration. There is a dorsal and ventral compartment. The reticulum has a honeycomb appearance, and the omasum consists of a series of about 100 longitudinal folds similar to the pages of a book. The nonglandular stratified squamous mucosa of the reticulum, rumen, and omasum can be acutely inflamed when the contents have an acid pH and the abnormal milieu permits bacterial and mycotic overgrowth.

The epithelial lining of the forestomach functions as a protective barrier for the forestomach and for the metabolism of ingesta and the absorption of volatile fatty acids. Because the reticulo-omasal orifice is more dorsal than the floor of the compartments, the reticulum can trap foreign bodies, especially dense metallic ones. These can irritate or penetrate the mucosa ("hardware disease"). Problems with motility and imbalances of rumen flora and fauna are the most frequent abnormalities of forestomach function. Often the changes in flora and fauna are precipitated by a change in ingested substrate promoting the growth of particular organisms. These changes alter ruminal pH and thus affect the integrity of the mucosal lining of the compartments of the forestomach or cause the production of excessive gas, resulting in distention.

Parts of compartment one (C1) (and of C2 and C3) of the camelid forestomach are lined by mucinous glandular epithelium. Concretions of ingesta are sometimes found within the saccules that contain the glands. The saccules are also the sites of water and other solutes. The nonglandular portions of C1 and C2 are lined by nonkeratinized stratified squamous epithelium. The forestomach of new world camelids contracts at two to three times the rate of other ruminants (and in reverse order), and with each cycle the saccules empty and refill. This results in high digestive efficiency across the saccules.

Ruminal tympany or bloat is, by definition, an overdistention of the rumen and reticulum by gases produced during fermentation. Mortality of affected animals is approximately 50%. A hereditary predisposition to bloat might exist in cattle because cases are on record of bloat in monozygotic twins. Bloat can be divided into primary tympany and secondary tympany.

Primary tympany is also known as legume bloat, dietary bloat, or frothy bloat. It generally occurs up to 3 days after animals begin a new diet. Certain legumes, such as alfalfa, ladino clover, and grain concentrates, promote the formation of stable foam. The nonvolatile acids of legume and ruminal fermentation lower the rumen pH to between 5 and 6, which is optimal for formation of bloat. Foam mixed with rumen contents physically blocks the cardia, preventing eructation and causing the rumen to distend with the gases of fermentation. Clinical signs include a distended left paralumbar fossa, a distended abdomen, increased respiratory and heart rates, and late in the disease, decreased ruminal movements. Death, when it occurs, is attributable to distention of the abdomen and compression of the diaphragm with resultant decreased pleural cavity size, respiratory embarrassment, and increased intraabdominal and intrathoracic pressure, resulting in decreased venous return to the heart, which becomes generalized congestion cranial to the thoracic inlet.

The lesions of primary tympany are often difficult to detect if there is an interval between death and postmortem examination, because the foam can collapse. Conversely, fermentation can occur after death in a nonbloat animal, resulting in the production of abundant gas. The most reliable postmortem indicator of antemortem bloat is the sharp line of demarcation between the pale, bloodless distal esophagus and the

## Pathologic Basis of Veterinary Disease, 4th Edition

congested proximal esophagus at the thoracic inlet. This line may sometimes form even after death before the blood clots. This division is known as a bloat line (Fig. 7-58).

Secondary tympany is caused by a physical or functional obstruction or stenosis of the esophagus resulting in failure to eructate. Vagus indigestion or other innervation disorders, esophageal papilloma, lymphosarcoma, and esophageal foreign bodies are examples of causes of secondary tympany.

**Fig. 7-58 Bloat line, esophagus and trachea at the thoracic inlet, cow.**

There is a sharp demarcation between the caudal (blanched) and the cranial (congested) mucosa of the esophagus (*arrow*). This demarcation is caused by compromised venous return, the result of a grossly distended rumen displacing the diaphragm cranially and causing increased intrathoracic pressure, thus preventing the flow of venous blood into the thorax. In this illustration, a similar demarcation can be seen on the mucosa of the trachea. The subcutaneous tissues of the neck and head are also congested. (Courtesy Department of Veterinary Pathology, Cornell University.)

327

7.2.7.4

### FOREIGN BODIES

328

Foreign bodies can collect or lodge in the rumen. These include trichobezoars (hair balls) and phytobezoars (plant balls). Trichobezoars are sometimes a sequelae to a habit of bucket-fed calves sucking on each other to satisfy their nursing instincts. Trichobezoars can form in utero because of hair circulating in the amniotic fluid and being swallowed by the fetus. Phytobezoars result from an excess of indigestible roughage.

Ingestion of nails and wire, common where straw and hay bales are bound by wire, can result in perforation of the wall of the reticulum with resultant reticulitis, peritonitis, or pericarditis (hardware disease) (Fig. 7-59). Often, in areas in the United States where ruminants are at high risk of hardware disease because of farming practices, magnets are placed in rumens to prevent the ingested wires and nails from penetrating the reticular mucosa. Occasionally, ruminants ingest plates from storage batteries and suffer lead poisoning.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.7.5

### INFLAMMATORY DISEASES

Inflammation of the rumen, rumenitis, is generally considered synonymous with lactic acidosis. Lactic acidosis is synonymous with grain overload, rumen overload, carbohydrate engorgement, and chemical rumenitis. All ruminants are susceptible. The pathophysiology of lactic acidosis usually involves a sudden dietary change to an easily fermentable feed or a change in the feed volume consumed. The latter scenario is most likely to occur during weather changes, especially among feedlot cattle when a sudden cooling rainstorm will stimulate food intake of cattle that had previously lost appetite due to high environmental temperatures and humidity.

**Fig. 7-59 Traumatic reticulitis, reticulum, cow.** Several ingested wires have perforated the wall of the reticulum (*arrow*) and lodged in the tunica muscularis. Each wire is surrounded by a sinus tract draining to the surface of the reticulum. A chronic ulcer has formed around each area penetrated by the wires. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Ruminal microflora is generally rich in cellulolytic gram-negative bacteria necessary for the digestion of hay. A sudden change to a highly fermentable, carbohydrate-rich feed promotes the growth of gram-positive bacteria, *Streptococcus bovis*, and *Lactobacillus* spp. The lactic acid produced by the fermentation of ingested carbohydrates decreases the ruminal pH below 5 (normal = 5.5 to 7.5). This acidic pH eliminates normal ruminal flora and fauna and damages ruminal mucosa. Increased concentrations of dissociated fatty acids lead to ruminal atony. Death, when it occurs, is due to dehydration secondary to the increased osmotic effect of ruminal solutes (organic acids) causing movement of fluids across the damaged ruminal mucosa into the rumen, acidosis (from absorption of lactate from the rumen), and circulatory collapse. Mortality among animals with lactic acidosis ranges from 25% to 90% and usually occurs within 24 hours.

At necropsy, the ruminal and intestinal contents are watery and acidic. Often abundant grain is found in the rumen. The mucosa of the ruminal papillae is brown and friable and detaches easily, especially from the ventral ruminal sac. Caution must be exercised in interpreting this latter finding as a lesion because the ruminal mucosa often detaches easily in animals that have been dead for even a few hours at high environmental temperatures. Hydropic change and coagulative necrosis of the ruminal epithelium followed by an influx of neutrophils are common microscopic lesions. Animals surviving lactic acidosis have stellate

## Pathologic Basis of Veterinary Disease, 4th Edition

scars develop, visible because of their color difference from the unaffected surrounding mucosa. Scars are pale; unaffected mucosa is dark brown to black.

Bacterial rumenitis generally occurs because of lactic acidosis or mechanical rumen injury. Bacteria that colonize the damaged rumen can be transported into the portal circulation and to the liver, resulting in multiple abscesses. *Arcanobacterium (Actinomyces) pyogenes* is a common cause of bacterial abscesses in the liver. *Fusobacterium necrophorum*, also transported from the rumen to the liver, results in necrobacillosis, which has distinctive liver lesions.

Mycotic infections of the rumen also occur because of damage to the ruminal mucosa caused by lactic acidosis and mechanical rumen injury. Mycotic rumenitis also results from the administration of antibiotics, usually in calves but also in adult cattle. The antibiotics reduce the number of normal flora and allow fungi to proliferate. In cases of mycotic rumenitis, lesions are generally circular and well delineated and are caused principally by infarction from thrombosis secondary to fungal vasculitis (Fig. 7-60). Offending fungi include *Aspergillus*, *Mucor*, *Rhizopus*, *Absidia*, and *Mortierella* spp. These fungi can spread to the placenta hematogenously and cause mycotic placentitis, which leads to abortions.

328

329

**Fig. 7-60 Mycotic rumenitis, rumen, calf.** Note the numerous well-demarcated foci of necrosis and hemorrhage (infarcts) in the ruminal mucosa that can be caused by angioinvasive fungi such as *Aspergillus*, *Mucor*, *Rhizopus*, *Absidia*, and *Mortierella* spp. This type of mycotic infection is usually preceded by a chemical (lactic acid) rumenitis (overeating). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Ruminal candidiasis occurs as an incidental finding at necropsy. There is usually an underlying debilitating condition, glucose therapy, or an antibiotic-induced kill-off of resident flora and fauna. Ruminal candidiasis is seldom diagnosed in a live animal.

### MISCELLANEOUS DISEASES OR CONDITIONS

Ruminal papillae vary in length, becoming longer with high-roughage diets (Fig. 7-61). Such diets also can cause the papilla to become tongue- or leaf-shaped. Animals consuming diets with less than 10% roughage can develop ruminal parakeratosis. These rumens have hard, brown, often clumped, papillae. This lesion has little to no clinical consequence.

Ruminal papillomas are viral-induced in some cases, but in certain countries, bracken fern has been implicated as a cause of these rumen neoplasms (Fig. 7-62).

Vagal indigestion results in a functional outflow problem from the forestomach. Damage to the vagus nerve can occur anywhere along its length and can result in functional pyloric stenosis. Causes of vagal indigestion include inflammation of the vagus nerve due to traumatic reticuloperitonitis, liver abscesses, volvulus of the abomasum, and bronchopneumonia. Mechanical obstruction of the forestomach or abomasal outflow can be due to lymphosarcoma or papillomas or to blockage following ingestion of indigestible or foreign materials. Diet and dwarfism are sometimes associated with vagus indigestion. Many cases are idiopathic. Clinical signs include ruminoreticular distention. The presence of abomasal distention is dependent on the precise location of the damage to the vagus nerve. Vagal indigestion is divided into four types, based on the anatomic location of the functional obstruction. Type I is usually due to inflammatory lesions around the vagal nerve and is a failure of eructation resulting in bloat. Type II is a functional or anatomic condition that results in failure of omasal transport into the abomasum. Usual causes are adhesions and abscesses on the medial wall of the reticulum associated with or secondary to traumatic reticuloperitonitis. Abomasal lymphosarcoma and physical obstruction of the omasal canal (e.g., neoplasia or ingested placenta) may also be causative. Type III is caused by physical impaction by roughage and thus is dietary in origin. Abomasum displacements and volvulus are also potential causes. Type IV is pregnancy related, perhaps as a result of shifting of position of the abomasum secondary to the expanding uterus.

329

330

Fig. 7-61 **Parakeratosis, reticulo-rumen, calf.** A diet that was almost devoid of roughage has resulted in atrophy and parakeratosis of ruminal papillae. Normal papillae are leaf shaped, but some of these papillae have become finger shaped, cauliflower shaped, or clumped. The parakeratotic epithelium has been stained brown to black by components of the feed because of the lack of abrasion by the ground feed. These lesions are most marked on the ventral floor of the ventral sac of the rumen. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-62 **Papillomas, rumen, cow.** Smooth-surfaced, squamous papillomas are present on the dorsal wall. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.7.7

### RUMINAL PARASITISM

Paramphistomiasis is a fluke infestation of the ruminant forestomach in warmer latitudes around the world. These trematodes are found in the genera *Paramphistomum*, *Calicophoron*, and *Cotylophoron*. They are similar in size and appearance to ruminal papillae (Fig. 7-63). Although the presence of adult organisms in the forestomach is usually of no clinical significance, heavy infestations of larvae in the proximal small intestine, before migration to the rumen and reticulum, can cause hypoproteinemia, anemia, and death. Larvae burrow deeply into, and sometimes through, the wall of the small intestine and can be found in the peritoneal cavity. The intermediate host is a snail. Cercariae encyst on aquatic vegetation and are eaten by the ruminant.

7.2.8

### STOMACH AND ABOMASUM

7.2.8.1

#### INTRODUCTION

Although some differences exist, the stomachs of the simple-stomached animals and the abomasum of ruminants (third compartment of new world camelids) are very similar in structure and function. A fundus and body make up the cranial portion lined by numerous spiral folds and produces acid and pepsin. The aboral portion, the pyloric part, is lined by epithelium with mucous-secreting glands and G cells that produce gastrin. Stomachs have an indigenous flora. Most of these organisms cannot be cultured by traditional methods.

**Fig. 7-63 Paramphistomiasis, rumen, cow.** The pink conical structures located in the center of the illustration are paramphistomes (ruminal flukes). They are considered to be innocuous, but massive numbers of immature flukes in the duodenum may cause a severe catarrhal duodenitis. Note the normal leaf-shaped ruminal papillae, indicative of a high-roughage diet. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 7.2.8.2 STRUCTURE AND FUNCTION

The gastric mucosa of simple-stomached animals contains numerous folds or rugae that can be flattened when the stomach is distended. Foveolas or gastric pits communicate with the lumen of the stomach and the transport gastric cell secretions. The glandular stomach functions in the enzymatic and hydrolytic digestion of ingested food substances. Epithelial cell types include columnar mucus and bicarbonate-secreting surface epithelial cells, mucous neck cells arranged in tubuloalveolar glands, acid-secreting parietal cells, pepsinogen-secreting chief cells, and neuroendocrine (enterochromaffin, argentaffin) cells.

Multiple submucosal lymphoid patches are present in monogastric animals. In ruminants a single lymphoid patch is present at the fold separating the omasum and abomasum.

In some species, such as the horse and rat, the cranial stomach (nonglandular part or pars nonglandularis) is lined by stratified squamous epithelium, whereas the distal portion (pars glandularis) is lined by glandular epithelium. In the horse, the dividing line between the two is called the margo plicatus. The pars nonglandularis in the pig is a small square to rectangular area of stratified squamous epithelium surrounding the esophageal entrance to the stomach.

### 7.2.8.3 DEFENSE MECHANISMS

The gastric mucosal barrier is of significant importance in preventing autodigestion and bacterial overgrowth. There is, however, a resident flora that is difficult to grow on artificial media. Microorganismal overgrowth is prevented under normal physiologic conditions by abomasal or gastric motility, prostaglandin E<sub>2</sub>, a protective layer of mucus and bicarbonate, secretory immunoglobulin A (IgA), transforming growth factor- $\alpha$ , epidermal growth factor, an extremely acid luminal pH, and an effective pyloric sphincter that prevents regurgitation into the stomach or abomasum of duodenal, hepatic, and pancreatic secretions. An intact epithelial layer and adequate blood flow also prevent acid-induced damage.

### 7.2.8.4 GASTRIC DILATION AND VOLVULUS

Simple gastric dilation occurs in a variety of animals and in human beings (Fig. 7-64). In dogs, particularly in the large, deep-chested breeds, the acute gastric dilation and volvulus syndrome occurs. This lesion is life threatening and should not be confused with simple gastric dilation that is common in young puppies after overeating. Predisposing factors to acute gastric dilation include a source of distending gas, fluid, or feed, obstruction of the cardia that prevents eructation, and emesis and obstruction of the pylorus that prevents passage of gastric contents into the small intestine. The source of gas is not well understood. Theories include gas production by *Clostridium perfringens*, spores of which are present in the feed, CO<sub>2</sub> from physiologic mechanisms of digestion, or simple aerophagia.

330

331

**Fig. 7-64 Simple gastric dilation, stomach, rabbit.** The stomach is markedly dilated and filled with gas, occurs most commonly following aerophagia or overeating, and is relieved by eructation or vomiting. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

The result of repeated episodes of gastric dilation is stretching and relaxation of the gastrohepatic ligament. Recurrent dilation combined with overfeeding, postprandial exercise, and perhaps a hereditary predisposition results in gastric rotation. Gastric rotation is recognized by splenic displacement and a twisted esophagus and results in vascular compression and decreased venous drainage and hypoxemia (Fig.s 7-65 and 7-66). The stomach generally is rotated clockwise on the ventrodorsal axis when the abdomen is viewed from the ventral surface. Rotation is 180 to 360 degrees. The combination of gastric hypoxemia, acid-base imbalance, obstruction of the pylorus and cardia, and increased intragastric pressure leads to antiperistaltic waves followed by atony, cardiovascular ischemia, arrhythmias, and shock. Decreased portal venous return leads to pancreatic ischemia and release of myocardial depressant factor, cardiac collapse, and death.

Epidemiologic evidence suggests that dry dog foods that list oils or fats among the first four ingredients increase the risk of gastric dilation and volvulus syndrome. Gastric dilation and volvulus is sometimes associated with gastric eversion or intussusception into the distal esophagus. This latter condition can also occur independently of gastric dilation and volvulus.

**Fig. 7-65 Schematic illustration, gastric dilation and volvulus, stomach, dog.** The stomach is distended with food and gas (*top example*). It rotates (*arrow*) on the mesenteric axis (*bottom example*) clockwise (180, 270, or 360 degrees on a ventrodorsal axis when the abdomen is viewed from the ventral surface), resulting in a gastric volvulus with an obstructed esophagus that prevents eructation and thus further contributes to gastric dilation. The spleen, attached to the stomach by the gastrosplenic ligament, rotates with the stomach and is thus folded back upon itself and located in the right cranial abdomen against the diaphragm (*bottom example*). The splenic vein is compressed, resulting in a congested spleen, because the arterial blood supply remains patent longer than venous drainage. (*Modified from Van Kruiningen HJ, Gregoire K, Meuten DJ: J Am Anim Hosp Assoc 10:294-324, 1974.*)

### 7.2.8.5

#### ABOMASAL DISPLACEMENT

Normally the abomasum lies over the xiphoid process at the abdominal ventral midline. Abomasal displacement is usually to the left side, although right-sided displacements also occur (Fig. 7-67). Left-sided

## Pathologic Basis of Veterinary Disease, 4th Edition

displacement of the abomasum is a generally nonfatal entity of high-producing dairy cattle during the 6 weeks following parturition. Strenuous activity can predispose nonpregnant cows to displacement. In the postcalving period, abomasal atony can occur as a result of heavy grain feeding (volatile fatty acids decrease motility) and hypocalcemia. Meanwhile, the gravid uterus may have displaced the rumen and abomasum cranially and to the left, rupturing the attachment of the greater omentum to the abomasum. The abomasum then occupies the cranial left quadrant of the abdomen and displaces the rumen medially. This change leads to partial obstruction of abomasal outflow. Metabolic acidosis contributes to rumen atony and impaired movement of ingesta. The associated hypochloremia is a result of HCl secretion and is common along with hypokalemia. Abomasal ulcers and peritoneal adhesions can result in chronic displacement.

331

332

**Fig. 7-66 Gastric dilation and volvulus, abdomen, dog.** The stomach is filled with gas and its serosa is congested. The duodenum and engorged spleen have been displaced to the right. (Courtesy Dr. A. Paulman, College of Veterinary Medicine, University of Illinois.)

Fifteen percent of abomasal displacements are right sided. The abomasum can be overdistended, displaced dorsally, and rotated on its mesenteric axis. Twenty percent of such cases lead to abomasal volvulus. Right-sided displacements occur in postparturient dairy cows and in calves.

Clinical features of displaced abomasums, whether right sided or left sided, include anorexia, cachexia, dehydration, lack of feces, ketonuria, and a characteristic high-pitched ping subsequent to percussion, over the abomasum. Idiopathic abomasal volvulus occurs occasionally in ruminants and calves (Fig. 7-68).

### 7.2.8.6

#### GASTRIC DILATION AND RUPTURE

Gastric dilation occurs in horses as a result of the ingestion of fermentable feeds or grain, a situation analogous to grain overload with lactic acidosis in cattle. Acute gastric dilation and rupture in equids occurs most frequently as a terminal event in intestinal obstruction and displacement. Because gastric dilation and rupture can occur after death, the diagnostic challenge is to determine if the rupture occurred antemortem or

## Pathologic Basis of Veterinary Disease, 4th Edition

postmortem. The only reliable indicator of the time of rupture, in relation to the death of the animal, is the presence of hemorrhage and evidence of inflammation, such as fibrin strands, along the margins of the rupture (usually the greater curvature), because such inflammatory responses occur only in live animals (Figs. 7-69 and 7-70).

Fig. 7-67 Schematic diagrams illustrating two possible modes of rotation of the omasum, abomasum, and cranial part of the duodenum in volvulus. 1, Normal relations; 2, simple dilation and displacement on the right; 3, 180-degree volvulus around the longitudinal axis of the lesser omentum, counterclockwise as seen from the rear; 2', 90-degree rotation of the abomasum in a sagittal plane, counterclockwise as seen from the right; 3', 180-degree rotation of the abomasum and omasum around the transverse axis of the lesser omentum, drawing the duodenum cranially, medial to the omasum; 4, 360-degree counterclockwise volvulus, final stage resulting from either mode of rotation. *D*, Duodenum; *E*, esophagus; *G*, greater omentum; *L*, lesser omentum; *O*, omasum; *P*, pylorus; *Q*, reticulum; *R*, rumen. (Modified from Habel RE, Smith DF: J Am Vet Med Assoc 179:447-455, 1981.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In Northern Europe, acute gastric dilation occurs in horses on pasture as part of the syndrome called grass sickness or dysautonomia. The esophagus and stomach are often dilated and atonic. Although serologic evidence suggests an association of grass sickness with *Clostridium perfringens* type A enterotoxin, noninflammatory degeneration of associated autonomic ganglia have also been described. This condition can be experimentally produced in the horse with whole blood from affected animals, suggesting that a soluble toxin may be causative.

332

333

**Fig. 7-68 Volvulus, abomasum, calf.** The volvulus took place at the omasal-abomasal junction, compromising the abomasum's venous return and resulting in severe passive congestion of the abomasal mucosa. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

**Fig. 7-69 Rupture, abomasum, calf.** Multifocal hemorrhages along the upper margin of the tear and subserosally adjacent to the greater curvature indicate that the rupture occurred antemortem. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Chronic gastric dilation is also associated with ingestion of poorly digestible substances. The habits of cribbing and aerophagia may also be contributory.

Dysautonomia also occurs in pet carnivores secondary to ganglionic death in cranial nerves, spinal nerves, and autonomic nerves. Associated ganglionic peptides are reduced in an amount consistent with the functional aberrations. Ganglioneuritis creates a similar syndrome to dysautonomia in a variety of species and is infrequently diagnosed. Gastrointestinal signs of dysautonomia include xerostomia, decreased anal tone, vomiting, and regurgitation.

**Fig. 7-70 Rupture, stomach, horse.** The hemorrhage visible on the right margin of the rupture indicates that the rupture occurred antemortem. Note also that the rent through the tunica muscularis is longer than that through the mucosa, which still covers the ingesta on the left and right sides. The mucosal and serosal surfaces are congested. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Chronic abomasal and/or rumen dilation may occur in cows with overeating disease, dystocia, exhaustion, poor-quality or frozen feedstuffs, abomasal ulcers with or without abomasal lymphoma, and vagal indigestion. A sequela of abomasitis may be a mycotic infection similar to that which occurs in the rumen (Fig. 7-71).

In monkeys, an increased frequency of acute gastric dilation often occurs during weekends, when there may be changes in feeding behavior secondary to nonfamiliar keepers. Studies have implicated *Clostridium perfringens* overgrowth secondary to an increase in fermentable feed consumption in the pathogenesis of gastric dilation in primates.

Chronic gastric dilation in canids is usually secondary to gastric ulcer, mural gastric lymphomas, uremia affecting gastric structure and function, pyloric stenosis or obstruction, acute gastric dilation, intervertebral

## Pathologic Basis of Veterinary Disease, 4th Edition

disc disease, or vagotomy. Chronic gastric dilation is characterized by reduced feed intake, diminished gastric motility, and increased gastric gas accumulation sometimes resulting in abdominal distention similar to that of bloat.

7.2.8.7

### IMPACTION

Impaction of the monogastric stomach and abomasum has a variety of causes. Lesions of the thorax such as pneumonia, pleuritis, lymphadenopathy, and lymphosarcoma can infiltrate and damage the vagal nerves. Roughage, hairballs, and other foreign materials also cause impaction. Gastric trichobezoars and phytobezoars of monogastric animals are similar to those that occur in the rumen (Fig. 7-72).

333

334

**Fig. 7-71 Mycotic abomasitis and omasitis, calf.** The mucosal surface of the abomasum has discrete and coalescing ulcers covered by yellow-white diphtheritic membranes and a red outer margin of active hyperemia and inflammation. These lesions are indicative of infarcts and are likely secondary to vasculitis and thrombosis by angioinvasive fungi such as *Aspergillus*, *Mucor*, *Rhizopus*, *Absidia*, and *Mortierella* spp. The diphtheritic membranes are a mixture of necrotic cellular debris from the infarct, inflammatory cells, and hyphae from the inciting fungus. *Inset*: Mycotic omasitis. The lesion is similar to the one in the abomasum. The diphtheritic membrane has been lost due to omasal peristalsis, but the necrotic center (infarct) and red outer margin of active hyperemia and inflammation are prominent. (**Figure**, courtesy College of Veterinary Medicine, University of Illinois. **Inset**, courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Abomasal emptying defect is principally a condition of Suffolk sheep 2 to 6 years of age. It is characterized by an impacted, dilated abomasum. Clinical signs include anorexia, weight loss, and increased ruminal chloride levels. The latter feature is believed to be secondary to abomasal reflux. Scattered chromatolysis and neuronal necrosis in the celiac and mesenteric ganglia are consistent with neurotoxicosis. The process is likely mediated by excitotoxins, although viruses have not been ruled out. Clusters of affected animals in a single flock are suggestive of an environmental causality. Inflammation is minimal. Abomasal emptying defect may be a form of acquired dysautonomia.

7.2.8.8

### INFLAMMATORY DISEASES

Inflammation of the simple stomach or abomasum, gastritis and abomasitis, respectively, must be distinguished from simple hyperemia and petechiae, which are often nonspecific agonal lesions. Gastritis is often associated clinically with vomiting, dehydration, and metabolic acidosis. Hemorrhage, edema, increased amounts of mucus, abscesses, granulomas, foreign body penetration, parasites, inflammatory cells of various types, erosions, ulcerations, and necrosis characterize the changes in the mucosal surface and subsequent inflammatory reaction.

**Fig. 7-72 Trichobezoar, stomach, rabbit.** The stomach is impacted with ingested hair. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

*Clostridium septicum* is a cause of hemorrhagic abomasitis with submucosal emphysema of sheep and cattle, a disease known as braxy. Although this disease is most common in the United Kingdom and Europe, it occurs in North America as well. Generally the disease follows ingestion of frozen feeds contaminated with the causative *Clostridium* spp. The lesions are produced by the exotoxin of the bacteria, and death therefore is due to an exotoxemia.

Sarcina-like organisms have been reported in association with abomasal bloat in several calves. Sarcinas are anaerobic, gram-positive, nonmotile cocci found in rafts or pockets. They are suspected gastric pathogens in a variety of animal species. The lesions are similar to braxy.

## Pathologic Basis of Veterinary Disease, 4th Edition

In many septicemias of pigs, bacterial emboli lodge in the vessels of the gastric submucosa and cause thrombosis resulting in hyperemia, hemorrhage, infarction, and ulceration. This occurs in salmonellosis, swine dysentery, Glasser's disease, and colibacillosis. Certain intoxicants such as vomitoxin produced by *Fusarium* spp. can cause similar lesions (Fig. 7-73).

A deep mycosis that causes a granulomatous gastritis is due to *Histoplasma capsulatum* (see Intestinal Diseases of Carnivores). Very rarely, *Mycobacterium tuberculosis* causes granulomatous gastritis in a variety of species. In granulomatous gastritis there is epigastric discomfort after eating (postprandial), emesis, progressive cachexia, weakness, vomiting of blood (hematemesis), and pyloric obstruction due to the space-occupying inflammatory reaction. In both histoplasmosis and tuberculosis, regional (gastric, splenic, and hepatic) lymph nodes may be affected. Nodular or diffusely thickened gastric and lymphoid lesions contain predominately macrophages. Mononuclear inflammatory cells, fibroblasts, granulocytes (including eosinophils), and multinucleate giant cells are also present. Often the causative organisms can be demonstrated within the granulomatous inflammation, but special stains such as acid-fast for mycobacteria and periodic acid–Schiff (PAS) reaction or Gomori's methenamine silver stain may be necessary to demonstrate fungi.

334

335

**Fig. 7-73 Acute “hemorrhagic gastritis,” stomach, pig.** The fundus of the stomach is hemorrhagic. This type of gastric change is often seen in the pig in acute septicemia, for example, from salmonella, and the severe congestion is attributed to venous infarction from endotoxemia. E, Esophageal os; P, pylorus. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Eosinophilic gastritis is uncommon in all species of domestic animals, but has been reported in pet carnivores and humans. The etiologic basis for this condition is in general poorly understood. There are three types of gastritis characterized by an influx of eosinophils.

A characteristic focal eosinophilic infiltrate is sometimes associated with trapped nematode larvae, especially *Toxocara canis*. Larvae of *Toxocara canis* pass to puppies through nursing, through fecal soiling of bedding, or from dirt or other fomites harboring eggs or larvae. It is the parasite's larval sheath, feces, and saliva that are antigenic. In dogs and cats, tissue reaction to these larvae results in epithelial cell hyperplasia, resulting in a polyp-like proliferation of the antral mucosa. Pyloric obstruction sometimes results.

In other cases of eosinophilic gastritis, the infiltration of eosinophils is more diffuse and is believed to be a hypersensitivity reaction. The offending antigen is not known. In many of these cases, there is a peripheral eosinophilia, especially when associated with eosinophilic infiltration of the small intestine (eosinophilic gastroenteritis). This form of eosinophilic gastritis may become transmural, with necrosis and scarring.

The third type, scirrhous eosinophilic gastritis of dogs and cats, for the most part has unknown causes. The fibrosis associated with scirrhous changes in the stomach and lymph nodes result in persistent emesis, weight loss, and malnutrition.

The gross lesions of eosinophilic gastritis are rather nonspecific and consist of diffuse or nodular mural thickenings. Microscopic lesions are characterized by infiltrates of eosinophils in the mucosa and the submucosa and are seen extensively through the muscle layers of the stomach and sometimes in segments of the small intestine and colon. In the dog, there is sometimes necroproliferative eosinophilic perivascularitis and eosinophilic lymphadenopathy. In the scirrhous form, the eosinophilic infiltrate is followed by transmural fibroplasia and scarring.

7.2.8.9

### HYPERTROPHIC OR HYPERPLASTIC DISEASES

Hypertrophic gastritis, characterized by thickened rugae, is the result of hyperplasia of the gastric glands. This effect is believed to be a response to chronic retention of gastric fluid and reflux of intestinal bile. Similar mucosal glandular changes are seen in immune-mediated lymphoplasmacytic gastritis of dogs. Hypertrophic gastritis has also been described in primates, horses, pigs, and rodents. The nematode *Noctia nocti* causes this lesion in the stomachs of monkeys. Equine hypertrophic gastritis is a focal or more diffuse lesion associated with the nematodes *Habronema* spp. and *Trichostrongylus axei*, respectively.

Chronic giant hypertrophic gastropathy of dogs affects the basenji, beagle, boxer, and bull terrier breeds, among others. The disease is similar to Ménétrier's disease in human beings. Clinical signs include weight loss, diarrhea, vomiting, and hypoproteinemia. The chronic gastritis results in increased mucosal permeability to serum proteins with subsequent protein-losing gastropathy. Unlike normal gastric mucosal folds, in giant hypertrophic gastropathy the mucosa does not flatten with distention of the organ (Fig. 7-74). Microscopically the mucosa is hypertrophic and hyperplastic. The incorporation of folds of submucosa and muscularis mucosa is variable, as is the presence of inflammatory cells. The cause of this condition is unknown.

7.2.8.10

### ULCERS AND EROSIONS

An ulcer is a mucosal defect in which the entire epithelial thickness, down to or through the basement membrane, has been lost. Penetration through the remaining tissue layers to the peritoneal cavity is termed a

335

336

## Pathologic Basis of Veterinary Disease, 4th Edition

perforating ulcer. Partial-thickness epithelial loss is termed an erosion. Chronic ulcers differ from acute ulcers by the presence of an indurated rim caused by fibrosis and attempts at epithelial regeneration. The identification of gastric ulcers is not challenging, both at necropsy and by endoscopy. They are sharply bordered cavities often coated with exudate. Thrombosis of blood vessels is sometimes associated with some ulcers in ruminants with mycotic vasculitis secondary to lactic acidosis. Thus, it is an infarct. The pathogenesis of most gastric and duodenal ulcers in human beings has been demonstrated to be a result of a helical bacterium. Although similar gastric *Helicobacter*-like organisms (GHLOs) are readily demonstrated in dogs and cats, their association with ulcer formation is not established. It appears that as many animals without gastritis or ulcers are as heavily colonized by these bacteria as are those animals with ulcers (Fig. 7-75). More than 90% of cats are infected with *Helicobacter* spp. *Helicobacter felis* can be cultured in vitro, but the noncultivable *Helicobacter heilmannii* is present most often. Pathologic and clinical outcomes depend on a number of bacterial virulence factors as well as on the host response to these agents. Investigations suggest there may be a link to *Helicobacter* presence and other disease entities, including coronary and neurologic disease.

**Fig. 7-74 Chronic giant hypertrophic gastropathy, stomach, dog.** A cerebriform mass of redundant mucosa is present in the center of the gastric mucosa. Chronic inflammation in the mass results in increased mucosal permeability to serum proteins and a subsequent protein-losing gastropathy. (Courtesy College of Veterinary Medicine, Cornell University.)

Theories abound as to the causes of most gastric ulcers in animals. None have been proven. There may be a heritable component to ulcer susceptibility. The conditions necessary for ulcer development boil down to an imbalance between acid secretion and mucosal protection. This imbalance occurs as a result of the following:

- Local disturbances or trauma to the mucosal epithelial barrier; this injury can be due to back flush of bile salts from the duodenum or ingestion of lipid solvents, such as alcohol.
- Normal or high gastric acidity

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- Local disturbances in blood flow (stress-induced and sympathetic nervous system-mediated arteriovenous shunts) resulting in ischemia
- Steroids and nonsteroidal antiinflammatory drugs (NSAIDs) that depress prostaglandin formation ( $\text{PGE}_2$ ,  $\text{PGI}_1$ ) or concentration, thus decreasing phospholipid secretions, which are protective

**Fig. 7-75 *Helicobacter* spp. infection, stomach, cat.** Numerous spiral bacteria are present in the superficial mucous layer. There is no inflammation in the adjacent mucosa; however, in some areas the epithelium is hyperplastic. H&E stain. *Inset:* The helical shape of the *Helicobacter* organisms is demonstrated with a Steiner's silver stain. (**Figure**, Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University. **Inset**, Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

All of the above mechanisms allow pepsin and hydrochloric acid into the submucosa.

Severe gastric hyperacidity and gastric ulcers is sometimes associated with islet cell tumors producing gastrin. Some of these gastrin-producing tumors arise in the duodenum, but the majority are endocrine or pancreatic in origin. These neoplasms release histamine into the blood stream, which binds to receptors on parietal cells of the stomach, increasing HCl secretion. The gastric ulceration produced associated with these tumors is known as Zollinger-Ellison syndrome.

In dogs, gastric ulceration causes vomiting, inappetence, abdominal pain, and anemia secondary to gastric bleeding (Fig. 7-76). Melena may also occur if the ulceration persists, and significant amounts of blood are lost to the gastrointestinal system. Gastric ulcers in dogs and cats are generally idiopathic but can occur in these animals with mast cell or other tumors.

336

337

**Fig. 7-76 Ulcer, stomach, dog.** The stomach contains a large volume of clotted and unclotted blood from a gastric ulcer (idiopathic). The hemorrhage was so severe that the dog died from exsanguination. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-77 Gastric ulcers, stomach, horse.** Administration of nonsteroidal antiinflammatory drugs (NSAIDs) has caused extensive ulceration of the stratified squamous epithelium of the nonglandular mucosa. The ulceration extends from the cardia (*center*) to the margo plicatus (*right*). (Courtesy College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Ulcers are idiopathic in foals. Foals with gastric ulcers may have abdominal pain, bruxism (grinding of the teeth), ptyalism, and gastric reflux and may lie in dorsal recumbency. Gastric ulcers associated with administration of NSAIDs are common in horses but are also described in other species given these drugs (Fig. 7-77). Equine gastric ulcer syndrome occurs in 40% to 90% of competitive and performance horses, with the most severe ulcers occurring in those animals that are worked the hardest. More than a third of horses used less strenuously develop mild ulcers.

**Fig. 7-78 Ulcers, abomasum, cow.** The ulcers consist of a central area of necrosis surrounded by an outer red margin characteristic of active hyperemia and inflammation. The discrete rounded outline of these ulcers suggests that they are infarcts, possibly from vasculitis and thrombosis caused by angioinvasive fungi. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-79 Perforating ulcer, abomasum, cow.** The rounded borders of the ulcer indicate an attempt at repair and therefore chronicity. Death was due to peritonitis. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Cattle with abomasal ulcers have partial or complete anorexia, decreased milk production, palpable discomfort to pressure applied to the right xiphoid area, and melena. In any species, the vomiting of coffee grounds-like material (hematemesis) or melena is highly suggestive of gastric ulcer disease. Abomasal ulcers of ruminants vary from subclinical to fatal (Figs. 7-78 and 7-79). In calves, ulcers are associated with dietary changes or mechanical irritation of the abomasum by roughage. Dietary changes involve substitution of roughage for milk or milk replacer, together with the associated stress. In dairy cattle, ulcers are associated with heavy grain feeding (lactic acidosis) at the time of parturition, displacement of the abomasum, BVD, impaction, torsion, and gastric lymphosarcoma.

337

338

**Fig. 7-80 Gastric ulcer (pars esophagea), stomach, pig.** This type of gastric ulcer occurs exclusively in pigs and most commonly in confined growing pigs. The lesion is limited to the stratified squamous epithelium surrounding the cardia (pars esophagea). Ulcers in this location characteristically have a multifactorial cause, including the ingestion of finely ground grain or pelleted feed (possibly deficient in vitamin E), fermentation of sugars in the feed, and stress of confinement rearing. These ulcers frequently bleed and can cause exsanguination. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

In pigs, gastric ulcers are common and occur in penned pigs fed finely ground grain. These ulcers always are limited to the stratified squamous epithelium of the esophageal portion of the gastric mucosa that surrounds the cardia (Fig. 7-80). Death can result from exsanguination into the gastric lumen. Evidence suggests that a high-carbohydrate diet is not sufficient alone to produce erosions and ulcers, but rather that the appropriate diet in combination with fermentative commensal bacteria, such as *Lactobacillus* and *Bacillus* spp., produce lesions.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.8.11 MISCELLANEOUS DISEASES AND CONDITIONS

Uremic gastritis occurs most frequently in carnivores as a result of chronic renal disease (Fig. 7-81). In ungulates, it is a rare event and is usually secondary to obstructive kidney disease (postrenal uremia). Uremic gastritis is characterized by mineralization of the glands, vessels, and interstitium of the gastric mucosa and sometimes results in ulcer formation.

Amyloidosis occasionally is present in the stomach in association with systemic amyloid infiltrates. Generalized AA amyloidosis with gastric deposits of amyloid has been reported in bats, Siamese and Abyssinian cats, goats, rhesus monkeys, sheep, and Siberian tigers.

#### Fig. 7-81 Uremic gastropathy (also called uremic gastritis), stomach, cat.

The major lesion here is congestion and edema of the gastric mucosa caused by injury to capillaries within the lamina propria associated with elevated concentrations of nitrogen-derived metabolic waste products in the systemic circulation from kidney failure. With chronicity, there is calcification of the gastric mucosa, visible as fine white stippling and lines in the mucosa (not shown here). (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

Pyloric stenosis can be due to an anatomic problem or an inability of the pyloric sphincter to function properly. This condition may be congenital or acquired. This lesion occurs most often in dogs (particularly brachycephalic breeds), Siamese cats, horses, and human beings. Congenital pyloric stenoses may be hereditary, at least in human beings. Pyloric stenosis is often first recognized in recently weaned animals by projectile vomiting, retention of gastric contents, gastromegaly, and the presence of strong peristaltic waves (Fig. 7-82). Pyloric muscular hypertrophy, variable submucosal edema, vascular ectasia, and degeneration of myenteric ganglion cells may be identified histologically. Functional pyloric stenosis can be a feature of vagus indigestion of ruminants. In general, the cause of pyloric stenosis is not well understood.

338

339

Fig. 7-82 **Pyloric stenosis, stomach, horse.** The probe passes through the narrowed pyloric canal. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-83 **Giant hypertrophic pyloric gastropathy, stomach, dog.** The mass of hyperplastic glandular tissue at the pylorus could be mistaken for a neoplasm. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Giant hypertrophic pyloric gastropathy, not to be confused with giant hypertrophic gastropathy of basenjis and other dogs, is a lesion seen most often in older small breed dogs. To the uninitiated, the gross and microscopic features of this pyloric lesion strongly imitate carcinoma (Fig. 7-83). Microscopically, there is notable foveolar and glandular hyperplasia with variable hypertrophy of smooth muscle, small mucosal erosions, and ulcerations. There is usually a lympho-plasmacytic infiltrate of variable degree. The cause of this condition is unknown.

### 7.2.8.12 PARASITES

#### 7.2.8.12.1 Horses

Many parasites cause disease of the stomach, especially in ungulates. Modern anthelmintics have made these diseases relatively easy to prevent and control both in individual animals and in herds.

Equine bots, *Gasterophilus intestinalis* and *Gasterophilus nasalis*, are commonly seen in animals on inadequate deworming regimens (Fig. 7-84). *Gasterophilus intestinalis* colonizes the stratified portion of the stomach. The adult fly lays eggs on the hairs of the distal limbs of the horse. *Gasterophilus nasalis* lays its eggs around the nose of the horse. The larvae hatch after being moistened and warmed by licking. They are swallowed and live in the duodenum. Both species attach to the mucosa via their anterior pincers. The larvae pass in the feces, pupate, and develop into flies.

**Fig. 7-84 Gasterophiliasis, stomach, horse.** Fly larvae (bots) of *Gasterophilus intestinalis* are attached to the epithelium of the nonglandular portion of the stomach. Note the muscular hypertrophy of the distal esophagus. Although not shown in this illustration, *Gasterophilus nasalis*, another similar equine gastric parasite, attaches to the epithelium of the glandular portion of the stomach. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-85 Focal granulomatous gastritis, *Draschia* brood pouch, stomach, horse.** A large parasitic brood pouch is present in the glandular mucosa adjacent to the margo plicatus (*right center of illustration*). Nematodes have been squeezed from the pouch and are visible on the surface (*arrow*). Histologically, the mucosa is expanded by focal granulomatous inflammation containing clusters of adult *Draschia megastoma*. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

*Draschia megastoma* is found in brood pouches in the glandular mucosa adjacent to the margo plicatus (Fig. 7-85). Infection is sometimes referred to as habronemiasis, based on antiquated taxonomic nomenclature in which the nematodes were classified as *Habronema* spp. Eggs produced in the cysts are extruded through a pore in the brood pouch to the gastric lumen. The eggs pass out with the feces and are consumed by fly larvae that are intermediate hosts. Both *Draschia* spp. and *Gasterophilus* spp. can cause gastric ulcers. Considering their location and means of survival in the stomach, it is remarkable that they do not cause serious damage more often.

339

340

### 7.2.8.12.2

#### Ruminants

*Haemonchus contortus*, the barber pole worm, is relatively common in ruminant abomasums. The common name of this parasite is related to the macroscopically visible entwining of the blood-filled intestine and white uterus in the female worm (Fig. 7-86). Hyperinfested pastures containing numerous third-stage larvae are the source of infection. Lambs are particularly at risk. Larvae on grasses are ingested by the host and enter the abomasum, where they may lie dormant within the gastric glands. After development to adults they enter the abomasal surface. Eggs pass in the feces, completing the life cycle. *Haemonchus* are blood feeders and can cause severe anemia, hypoproteinemia, and resultant edema. This edema is characteristically present in the intermandibular space resulting in a physical resemblance to a bottle ("bottle jaw"). As with any process resulting in anemia and hypoproteinemia, there are pale mucus

## Pathologic Basis of Veterinary Disease, 4th Edition

---

membranes, stunting, and diarrhea. Diagnosis is by fecal egg counts and, at necropsy, by semiquantification of abomasal parasite load along with the attendant lesions of anemia and hypoproteinemia.

In temperate climates, ostertagiosis is considered the most important parasitic disease in cattle (*Ostertagia ostertagia*) and small ruminants (*Ostertagia circumcincta*). Affected animals are unthrifty. *Ostertagia* spp. have a direct life cycle similar to that of *Haemonchus* spp. The nematodes are smaller than those of *Haemonchus* and are uniformly brown. Third-, fourth-, and fifth-stage larvae reside in the abomasal gastric glands. *Ostertagia* spp. are often present along with *Trichostrongylus* spp. in other gastrointestinal locations. Intercurrent gastrointestinal parasitism with other trichostrongyles has an additive effect on clinical symptomatology. Unthriftiness, lack of proper mentation, diarrhea, hypoproteinemia, and ventral edema may result. The multinodular appearance of the abomasum of heavily infested animals resembles Morocco leather (Fig. 7-87). This cobblestone appearance is due to mucous cell hyperplasia and lymphoid nodules in the abomasal submucosa elevating the overlying epithelium. Differential diagnoses include lymphosarcoma.

**Fig. 7-86 *Haemonchus contortus*, abomasum, sheep.** The white spiral reproductive tract wrapped around the blood filled intestine is responsible for the striped appearance, hence the common name “barber's pole worm.” (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-87 **Ostertagiosis, abomasum, cow.** The granular Moroccan leather appearance of the abomasal mucosa is characteristic of chronic ostertagiosis and is due to epithelial hyperplasia of the gastric glands, which may also contain *Ostertagia* larvae. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Abomasitis produced by *Ostertagia* spp. is characterized by an infiltration of mononuclear inflammatory cells and eosinophils. There are also increased numbers of globule leukocytes, a decrease in the number of parietal and chief cells, and hyperplasia of abomasal mucous cells. *Ostertagia* spp. are visible macroscopically. The nematodes are brown, are smaller than those of *Haemonchus contortus*, and are present within the gastric glands and mucosal nodules formed as a result of the host's response to the parasite's presence.

### 7.2.8.12.3

#### Pigs

*Hyostrogylus rubidus* of pigs is a gastric parasite that causes a thickening of the mucosa, with mucus accumulation and submucosal pockets. The parasite is threadlike and red. Clinically, hyostrogylus is associated with the "thin sow syndrome." Grossly the gastric mucosa is thickened, catarrhal, and somewhat cobblestone. Microscopically, there is mucus metaplasia of parasitized and adjacent gastric glands. Submucosal lymphoid follicles develop in chronic infections.

### 7.2.8.12.4

#### Carnivores (Dogs and Cats)

Several genera of nematodes, principally *Ollulanus*, *Gnathostoma*, and *Cylicospirura*, rarely cause gastritis in dogs and cats.

340

Fig. 7-88 **Physalopteriasis, stomach, dog.** Stout coiled nematodes, *Physaloptera canis* are firmly attached to the gastric mucosa by dentate pseudolabia. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-89 **Leiomyoma, stomach, dog.** This tumor arose from smooth muscle in the tunica muscularis and is covered by intact mucosa. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

*Physaloptera* spp. are often thought of as gastric parasites of carnivores because they are sometimes found in the stomach on endoscopic examination or at necropsy. They are occasionally responsible for vomiting. They appear similar to ascarids but generally attach by anterior hooks to the proximal duodenal mucosa at the gastric valve (Fig. 7-88). Intermediate hosts are coprophagous beetles.

**Fig. 7-90 Lymphoma (lymphosarcoma), stomach, cat.** A large expansile mass is present in the submucosa of the stomach (*top edge*) and is covered by an intact mucosal epithelium. Note the other lymphomatous mass, which is ulcerated (*lower right*). This latter lesion is somewhat atypical of this disease, because ulceration is uncommon and occurs in late-stage disease when the mass is quite large and protrudes into the gastric lumen. In most cases of gastric lymphoma, the mucosal epithelium is intact and not ulcerated. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-91 **Lymphoma (lymphosarcoma), stomach, horse.** Large smooth-surfaced submucosal nodules, two of which have a central hemorrhagic ulcer, are present in the glandular portion of the stomach. Ulcers in the stratified squamous portion of the stomach are sites of *Gastrophilus intestinalis* attachment. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.8.13

### NEOPLASIA

Gastric neoplasia, although uncommon, manifests in different ways in domestic animals. Leiomyoma and more rarely leiomyosarcoma arise from the tunica muscularis (Fig. 7-89). Lymphosarcoma can be primary, metastatic, or multicentric in origin (Figs. 7-90 and 7-91). In cattle, lymphosarcoma is often caused by the bovine leukemia virus and has a predilection for the abomasum and the right atrium and uterus (Fig. 7-92). Squamous cell carcinoma of the stratified squamous (esophageal) portion of the stomach is relatively common in the horse (Fig. 7-93). Glandular neoplasms, adenomas, and adenocarcinomas occur in all species but are seen most often in dogs and cats.

341

342

Fig. 7-92 **Lymphoma (lymphosarcoma), transverse section of the abomasum, cow.** This cross section demonstrates a white, space-occupying submucosal mass. The intact mucosa is located at the top of the specimen. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

### 7.2.9 INTESTINE

#### 7.2.9.1 INTRODUCTION

The intestines might be thought of as a tube within the body cavity that carries material (ingesta) through the body. The overall anatomic and histologic organization of this digestive tube is demonstrated in [Fig. 7-94](#). By the action of enzymes, resident flora, and added secretions, ingesta are broken down, useful substances are absorbed into the body, and waste products are excreted. To perform these functions, the intestine needs a very large surface area. Creation of this surface area is accomplished by coiling the intestine in the abdomen. Herbivores have longer intestines than carnivores or omnivores and need a fermentation vat, either the rumen or cecum, to digest cellulose. In addition to its length, the intestinal mucosa is thrown into numerous folds that contain villi that notably increase the number of cells contacting the ingesta ([Fig. 7-95](#)). Finally, each enterocyte has a microvillous border, further increasing the surface area available for digestive and absorptive processes. Damage to any of these structures can result in intestinal dysfunction and resultant diarrhea.

#### 7.2.9.2 STRUCTURE AND FUNCTION

The intestinal mucosa is composed of epithelial cells lining the intestinal lumen and mesenchymal cells of the lamina propria and muscularis mucosa. An understanding of these cell types and their functional roles in digestion and absorption is important in understanding the mechanisms of intestinal disease. Similarly, an understanding of the biology of these cell types is important in predicting clinical outcomes and therapeutic strategies for intestinal disease. The structure and function of the intestine and categorization of veterinary pathogens by cell-type tropism was admirably described by Dr. H.W. Moon in both editions of *Cell Pathology*, by Dr. N. Cheville.

##### 7.2.9.2.1 Epithelial Cells

There are six types of epithelial cells lining the intestine. These absorptive epithelial cells are called enterocytes, undifferentiated or crypt epithelial cells, goblet cells, Paneth cells, enterochromaffin (neuroendocrine, argentaffin) cells, and M cells ([Fig. 7-96](#)).

Enterocytes are tall and columnar with luminal microvilli. They contain a surface glycocalyx that houses the digestive and absorptive enzymes. The mature cells do not proliferate, but they provide feedback inhibition of mitosis of the crypt cells by chalone. Many nutrients are absorbed through the lateral intercellular spaces between cells. Enterocytes move up the crypt and intestinal villus to the extrusion zone at the villus tip, where effete enterocytes are discarded into the fecal mass. The turnover rate for enterocytes is the most rapid of any fixed-cell population in the body. In neonatal pigs, for instance, the turnover rate is 7 to 10 days. In 3-week-old pigs that have achieved climax flora, that rate accelerates to 2 to 3 days.

Undifferentiated crypt epithelial cells have little or no digestive capability. They are the progenitor cells that replace all of the other epithelial cell types. They have short, sparse microvilli. Crypt cells are considered the source of secretory component that acts as a receptor for IgA and immunoglobulin M (IgM) produced by plasmacytes in the intestinal lamina propria. The migration rate of crypt cells up the villus is dependent on several factors, one of which is an adaptation to gut microflora. In germ-free or

342

343

## Pathologic Basis of Veterinary Disease, 4th Edition

gnotobiotic animals, the enterocyte replacement rate is similar to that of the neonate. Crypt cells are considered a source of chloride ion secretion into the intestinal lumen.

**Fig. 7-94 Schematic diagram of the anatomic and histologic organization of the digestive tube. A, Entire digestive tube. B, Higher magnification of the jejunum and ileum. (A, From Kierzenbaum AL: Histology and cell biology: an introduction to pathology, St Louis, 2002, Mosby.)**

Goblet cells function in mucus secretion. They occur in both villous and crypt regions. Their numbers tend to increase caudally through the intestine.

Paneth cells are located near the crypt base in some species, notably primates, horses, and rodents. Paneth cells are considered to have both secretory and phagocytic functions. They produce cryptdin and lysins. These substances are toxic to bacteria and probably protect the proliferating crypt cells from infection. Collectively, Paneth cells consist of a cellular mass similar to that of the pancreas. It has been suggested that Paneth cells play a role in elimination of heavy metals because they are selectively damaged by methylmercury.

## Pathologic Basis of Veterinary Disease, 4th Edition

Enterochromaffin cells, also known as argentaffin cells because of their affinity for silver, are enteroendocrine cells. They occur primarily in the crypts and produce serotonin, catecholamines, gastrin, somatostatin, serotonin, cholecystokinin, secretin, bombesin, enteroglucagon, and likely others. They secrete these products into the tissue rather than the gut lumen and thus are truly endocrine. Occasionally, they form neoplasms called carcinoids.

343

344

**Fig. 7-95 Organization of the intestine.** The digestive and absorptive surfaces of the intestine are markedly increased by the presence of villi and microvilli on the enterocytes. **A**, Intestinal villus. Villus epithelial cells are present on a basement membrane (not seen) on a core of lamina propria. H&E stain. **B**, Small intestine, intestinal villi, scanning electron microscopy. Carbon sputter coat. **C**, Enterocyte microvilli. TEM. Uranyl acetate and lead citrate stain. (**A**, **B**, and **C**, From Damjanov I, Linder J: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

M cells are so named because they have a microfolded or membranous surface. They form the dome epithelium that covers the gut-associated lymphoid tissue (GALT). They serve important functions in the uptake of antigens from the intestinal lumen and in the transport of these antigens to the GALT. M cells also serve as a portal of entry for some pathogens, including bacteria such as *Salmonella*, *Yersinia*, and *Rhodococcus* spp. and some viruses, such as BVD virus.

### 7.2.9.2.2

#### Mesenchymal Cells

Mesenchymal cells reside in the lamina propria. Their numbers increase with exposure to antigen, although there is a resident population of these cells in normal animals. The intestinal lymphoid tissue is

## Pathologic Basis of Veterinary Disease, 4th Edition

25% of the body's lymphoid mass (Fig. 7-97) and consists of those in the lamina propria and the GALT. This volume is larger than that of the spleen. In spite of the fact that the average person ingests 700 tons of antigens in a lifetime, the gut is adept at not responding to these food antigens. Data are beginning to accumulate identifying the different T-lymphocyte types in the lamina propria.

Neutrophils are transient within the lamina propria of the intestine. Neutrophils are short-lived in the blood and tissues; their normal route of removal from the body is to migrate through the wall of the alimentary tract to the lumen and be digested or excreted from the body via feces.

Eosinophils, when present in the intestinal lamina propria and submucosa, indicate a hypersensitivity reaction, often to food antigens or parasites.

Globule leukocytes are large granular lymphocytes that are interepithelial or within the lamina propria. They are found in all species and occasionally form neoplasms, most notably in the cat. The normal function of these cells is unknown.

### 7.2.9.3

#### DEFENSE MECHANISMS

Defense mechanisms of the intestinal tract are diverse. They include indigenous (nonpathogenic) bacterial flora, intestinal and extraintestinal secretions, gastric acidity, intestinal motility, epithelial cell turnover, bile salts, immunologic mechanisms, and, although a secondary mechanism, the Kupffer cells of the liver.

Secretions of the oral cavity, saliva, and intestine, called mucins, inhibit the adherence of organisms to the mucosa of the alimentary system.

Normal gastric acidity kills many organisms before they have the chance to interact with enterocytes. Very young animals are achlorhydric; thus they may be more susceptible to some organisms, such as pathogenic *Escherichia coli*.

Helical bacteria in the stomach are the single greatest cause of gastric ulcers in human beings. Although similar organisms occur in the stomachs of domestic animals, particularly carnivores, their role in gastritis of animals is less certain. Normal gastric acidity apparently does not kill all potentially pathogenic bacteria (helical bacteria) in the stomach and proximal small intestine of domestic animals.

Indigenous (nonpathogenic) bacterial flora competitively bind to putative attachment sites on the enterocytes thus preempting pathogen attachment. They also compete for substrate with pathogens and alter the microenvironmental pH, making competitive growth difficult. In addition, they produce inhibitory growth substances that are toxic to other bacteria called bacteriocins. Colicins are bacteriocins produced by *Escherichia coli*.

Intestinal peristalsis is protective in that loss of motility may lead to bacterial overgrowth in the intestine and increased susceptibility to toxins that are not moved out of the gut. Diarrhea can be in part a defense mechanism that rids the body of bacteria and toxins.

Epithelial cells of the intestine have the greatest turnover rate of any cell population in the body. In effect this means that pathogens with a life cycle that exceeds that of the enterocytes will likely not be successful because their host cell will slough before the pathogen can reproduce.

Bile salts inhibit the growth of many organisms, and the Kupffer cells of the liver act as a secondary line of defense. Because all the blood from the intestine percolates through the hepatic sinusoids, the Kupffer cells

344

345

## Pathologic Basis of Veterinary Disease, 4th Edition

are perfectly positioned to phagocytose bacteria and endotoxins with which they come in contact. In pigs, goats, and cattle (artiodactyls), these functions are performed by intravascular pulmonary macrophages.

**Fig. 7-96 Schematic illustration of the epithelial cell types of the small intestine.** Progenitor cells, located in the intestinal crypts, give rise to all other epithelial cell types lining the crypt and covering the villi. (From Damjanov I, Linder J: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

**Fig. 7-97 Normal gut-associated lymphoid tissue, intestine, pig.** The lymphoid tissue on the antimesenteric surface of the intestine is outlined by arrows and makes up one quarter of the animal's total lymphoid mass. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Secretory IgA and IgM constitute very important mechanisms of humoral immunity and function largely to prevent attachment of pathogens to intestinal epithelium. Crypt epithelial cells produce the secretory component of IgA.

Bacterial growth is inhibited by lactoferrin and peroxidase from the pancreas and lysozyme from Paneth cells.

### 7.2.9.4

#### DIARRHEA

### 7.2.9.4.1

#### Pathogenesis

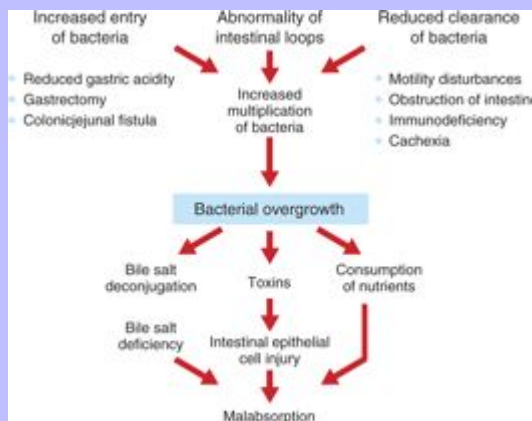

Diarrhea is defined as secretion of abnormally fluid feces accompanied by an increased volume of feces and an increased frequency of defecation. There are four major mechanisms by which diarrhea may occur:

- Malabsorption with or without bacterial fermentation leading to osmotic diarrhea. Generally, this is a problem of the small intestine, but secondary colonic malfunctions can occur because of malabsorption of bile salts and fatty acids that stimulate fluid secretion in the large intestine.
- Hypersecretion by a structurally intact mucosa. This activity results in a net efflux of fluid and electrolytes independent of permeability changes, absorptive capacity, or exogenously generated osmotic gradients.
- Exudation caused by increased capillary or epithelial permeability (protein-losing enteropathy).
- Hypermotility generally is involved in diarrhea, but usually not as a primary mechanism in domestic animals. Hypermotility is defined as an increased rate, intensity, or frequency of peristalsis. Theoretically, with decreased mucosal contact time, digestion and absorption of

345

nutrients should be less efficient. It is suspected that decreased motility in some diseases allows for increased bacterial proliferation (Fig. 7-98). Conversely, some enterotoxins can stimulate intestinal motility.

**Fig. 7-98** Schematic diagram of the mechanism of how intestinal bacterial overgrowth causes malabsorption and diarrhea. (From Damjanov I, Linder J: Anderson's pathology, ed 10, St Louis, 1996, Mosby.)

As might be expected, the pathogenesis of diarrhea is much more complicated than as just explained. Involved are a complex interplay of cells and factors that are currently being elucidated by a variety of molecular techniques. For example, when a pathogen invades an enterocyte, the pathogen can release an enterotoxin. This toxin causes the enterocyte to release cytokines, particularly interleukin-8 (IL-8). These cytokines activate resident macrophages and recruit new macrophages into the lamina propria from the blood. The activated leukocytes release soluble factors (histamine, serotonin, adenosine) that increase intestinal secretion of chloride ions and water and inhibit absorption.

Other factors (prostaglandins, leukotrienes, platelet-activating factor) act on enteric nerves to induce neurotransmitter-mediated intestinal secretion. Cell damage is possibly a consequence of inflammation mediated by T lymphocytes or proteases and oxidants secreted by mast cells. T lymphocytes also may affect epithelial cell maturation, causing villous atrophy and crypt hyperplasia. Cell death can result from pathogen invasion into enterocytes, multiplication of the pathogen, and extrusion of the affected enterocytes. These changes lead to notable distortion of villous architecture with a lack of absorptive mature enterocytes accompanied by nutrient malabsorption and osmotic diarrhea.

Additionally, there are nonintestinal causes of diarrhea that must be considered in addition to diseases of the intestine. Among this group are hyperthyroidism, Addison's disease, pancreatic insufficiency, pancreatitis, chronic renal failure, and others. These diseases are discussed in their respective chapters of this book.

## 7.2.9.4.2

### Consequences

The consequence of excess fluid loss in the feces through diarrhea is dehydration. Dehydration results in hypovolemia. Hypovolemia results in hemoconcentration that results in inadequate tissue perfusion.

## Pathologic Basis of Veterinary Disease, 4th Edition

Energy therefore is generated in tissue by anaerobic glycolysis. The resultant hypoglycemia leads to ketoacidosis. Acidosis is, by definition, a reduction in blood and tissue pH. Acidosis causes a reduction in pH-dependent enzyme system functions. Acidosis is compounded by fecal bicarbonate loss in diarrhea and the results of inadequate renal excretion of hydrogen ions and inadequate absorption of bicarbonate, which is a late effect of inadequate renal perfusion. The resultant electrolyte imbalance results in an increase in intracellular hydrogen ion concentration and a decrease in intracellular potassium ion concentration. The imbalances decrease neuromuscular control of myocardial contraction, leading to a further decrease in tissue perfusion. A vicious cycle results, culminating in hypovolemic shock.

7.2.9.5

### DEVELOPMENTAL ANOMALIES

Occlusion of the intestinal lumen due to anomalous development of the intestinal wall is called atresia (Fig. 7-99). Atresia is generally named for the part of the bowel that is occluded, such as atresia ani or atresia coli.

346

The causes of atresia in domestic animals are not completely understood, but it can be a result of mechanical lesions to blood vessels in a portion of the gut, such as caused by malpositioning, that compromises circulation and results in vascular accidents and ischemia. Release of meconium into the abdominal cavity of the fetus may result in sterile peritonitis and may be responsible for some cases of atresia, such as in cystic fibrosis of human beings. In still other cases, the embryonic cells that occlude the lumen fail to break down, resulting in atresia. The end result is segmental atresia in which a segment of the bowel is either entirely missing or completely occluded because of a lack of epithelial development and confluence between two contiguous portions (Figs. 7-100 and 7-101).

347

**Fig. 7-99 Schematic illustration of the types of stenosis and atresia. A, Stenosis. B, Stenosis with partial membrane. C, Membrane atresia. D, Cord atresia. E, Blind end atresia. F, Christmas tree atresia (1, jejunum; 2, ileum; 3, colon; 4, ileocolic artery). (A through F, From van der Gaag I, Tibboel D: Vet Pathol 17(5):565-574, 1980.)**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Fig. 7-100 **Abdominal distention, atresia coli, feeder pig.** This pig has been unable to defecate since birth because of an atretic developmental malformation of the distal colon. Note the greatly distended abdomen. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Meckel's diverticulum is a remnant of the omphalomesenteric duct. It is near the termination of the ileum and represents the stalk of the yolk sac. Generally, it disappears after the first trimester of gestation. It can persist in all mammalian species and although blind-ended, should not be confused with the cecum.

Fig. 7-101 **Atresia coli, colon, cow.** There is a blind-ended atretic segment of the spiral colon. The smaller segment at the left of the photograph is distal, the terminal part of the colon. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-102 **Megacolon, colon, cat.** This disease may be congenital due to a lack of intestinal innervation or atresia of the distal colon or anus. It can also be acquired secondary to nerve injury. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Megacolon, as its name implies, is a large, usually fecal-filled colon (Figs. 7-102 and 7-103). It occurs in pigs, dogs, cats, overo foals, and human beings. It may be caused by a congenital lack of myenteric plexuses (Hirschsprung's disease) secondary to the failure of migration of neuroblasts from the neural crest to the colorectal myenteric plexuses.

347

348

Fig. 7-103 **Megacolon, colon, dog.** The large colon from the cecum (C) to the anus is dilated with feces. In dogs, this disease has pathogenesises similar to those described in cats (Fig. 7-102). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

The equine overo pattern of spotting is defined by white patches of epidermis on the ventral or lateral abdomen that extend dorsally up to, but do not include, the dorsal midline. The epidermis is also nonpigmented on the lateral neck and flank. The overo pattern typically includes at least one pigmented leg. Affected foals are white and appear normal at birth. They do not pass meconium; subsequently they have colic develop and die. These white foals are nonperistaltic because of absence of the myenteric (Auerbach's) plexus or submucosal (Meissner's) plexus particularly in the colon and rectum. Thus these anomalies can be termed aganglionosis. A congenital aganglionic megacolon is contracted and nonperistaltic. Dilation or megacolon occurs proximal to the aganglionic section of the gut.

Acquired megacolon is secondary to damage to the colonic innervation. Such events are usually traumatic and most common in carnivores struck by automobiles. Atresia ani can also result in megacolon.

### 7.2.9.6

#### INTESTINAL OBSTRUCTION

Mechanical obstruction of the intestinal tract occurs in all species of domestic and wild animals. Although foreign bodies of all types have been removed from animals at surgery, the long-term systemic effects of some foreign bodies are also important. These include copper and zinc toxicosis from ingestion of coins in dogs, seals, ruminants, and horses, and lead poisoning in cattle from ingestion of old batteries. Primates caged in outdated facilities with lead paint or lead bars can also succumb to lead poisoning. *Pythium insidiosum* infection has caused intestinal obstruction in a puppy.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.6.1

### Enteroliths and Impaction

Enteroliths are rare in species other than the horse, with an increased incidence in the Arabian breed. Generally, affected animals are more than 4 years old. The stones are usually formed by ammonium magnesium phosphate (struvite) and collect around a small central nidus, often a metallic foreign body (Fig. 7-104). Enteroliths vary greatly in size from several centimeters in diameter to greater than 20 cm, and they can weigh several kilograms. They generally lodge at the pelvic flexure or transverse colon. Diets high in magnesium and phosphorus predispose to enterolith formation. In the past, millers' horses (grain and feed mills) had access to large amounts of inexpensive bran, and thus their horses were more prone to enteroliths. In California, the feeding of high-protein, magnesium-rich alfalfa hay may partially explain the higher incidence of enteroliths in California equids.

The presence of aggregated ingesta that cannot move along the intestinal tract (impaction) occurs in all species. It is especially common in horses following anthelmintic administration and is the result of the rapid die-off of large numbers of nematodes, particularly ascarids (Fig. 7-105). Cecal impaction occurs in old horses because of a high-roughage (indigestible) diet, debility, or poor dentition caused by a lack of mechanical leveling of the teeth (floating). Fibrous ingesta can also result in ileal impaction. Large amounts of ingested sand can accumulate anywhere in the equine colon, resulting in impaction.

348

349

**Fig. 7-104 Enterolith, horse.** This cross section demonstrates concentric laminations. A metallic nidus was present in the center of the enterolith. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-105 **Ascarid impaction, jejunum, horse.** Impaction was the result of a rapid “die off” of the ascarids as the result of administration of an anthelmintic. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-106 **Stricture, intestine, horse.** The dilated intestine (D) is proximal to the stricture. Such strictures can be caused by penetrating or nonpenetrating wounds of all kinds from the luminal side or to vascular injury. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.6.2

### Strictures with Obstruction

Strictures (luminal narrowing) due to penetrating or nonpenetrating wounds of all kinds or to vascular injury can obstruct the intestine (Fig. 7-106). For example, rectal stricture is a sequela of salmonellosis in pigs and is due in part to thrombosis of the cranial hemorrhoidal artery and lack of collateral circulation (Fig. 7-107) that could otherwise allow the intestinal segment to remain viable.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.6.3

### Intussusception

When one segment of intestine becomes telescoped into the immediately distal segment of intestine, the lesion is called an intussusception (Figs. 7-108 and 7-109). The intussusceptum is the trapped segment and the intussusciens is the enveloping portion of the intestine. The cause is generally unknown but is thought to be associated with intestinal irritability and hypermotility. Irritability and hypermotility can occur secondary to enteritis, irritation that is caused by parasites of all sorts, and general debility. Foreign bodies, neoplasms, and some parasites, such as the nodular worm of sheep (*Oesophagostomum* spp.), by means of the subserosal nodules it produces, can provide a toehold for the intestine to telescope into itself. In the dog, intussusception of the intestine has been related to, or caused by, handling of the small intestine during surgery, hypertrophied lymphoid nodules, and granulomas secondary to inflammatory and parasitic diseases, linear foreign bodies (string) (Fig. 7-110, A), and ascarids.

**Fig. 7-107 Stricture, colon, pig.** This lesion in pigs has been attributed to thrombosis of the cranial hemorrhoidal artery from vasculitis and thrombosis caused by salmonella. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In bovids and equids, tumors, abscesses and granulomas may be causes of intussusceptions. In equids, verminous arteritis may uniquely cause intussusceptions. Ileoileal, ileocecal, cecocolic, and cecocolic intussusceptions are sometimes associated with *Anoplocephala perfoliata*. Rarely, duodenogastric and gastroesophageal intussusceptions occur.

Clinical features of intussusception are similar to those of intestinal obstruction. In small animals with thin abdominal walls, they can sometimes be palpated. Intussusceptions are enlarged, thickened segments of intestine that vary in length. Intussusceptions are grossly swollen, doughy-feeling segments of the intestine. They resemble the folds of an accordion (Fig. 7-110, B). Red to black discoloration depends on the degree of vascular compromise, ranging from congestion to hemorrhage and necrosis. The mesenteric attachment of the intussusceptum may be seen extending from the lesion. Ischemic necrosis, congestion, and edema may occur in both the intussusceptum and intussusciens.

Because peristalsis continues after death, intestinal invaginations can occur after death. Before attributing death to intestinal obstruction caused by intussusception, there is a need to determine if the intussusception took place before or after death. Because inflammation only occurs in the living organism, postmortem invaginations are easily reduced because there are no adhesions and they are not accompanied by hyperemia or fibrin on the peritoneal surfaces, which remain smooth and glistening. On rare occasions, antemortem intussusceptions spontaneously reduce by sloughing of the infarcted intussusceptum, which then passes in the feces. Often the site of sloughing is replaced with fibrous tissue, and a circumferential scar or stricture forms.

349

350

Fig. 7-108 **Intussusception.** **A**, Schematic diagram showing the anatomic positioning of small intestinal segments in an intussusception. **B**, Longitudinal section of small intestinal intussusception demonstrating the position of the intussusceptum (trapped segment) and the intussusciens (the enveloping portion) of the small intestine. Boosinger, College of Veterinary Medicine, Auburn University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

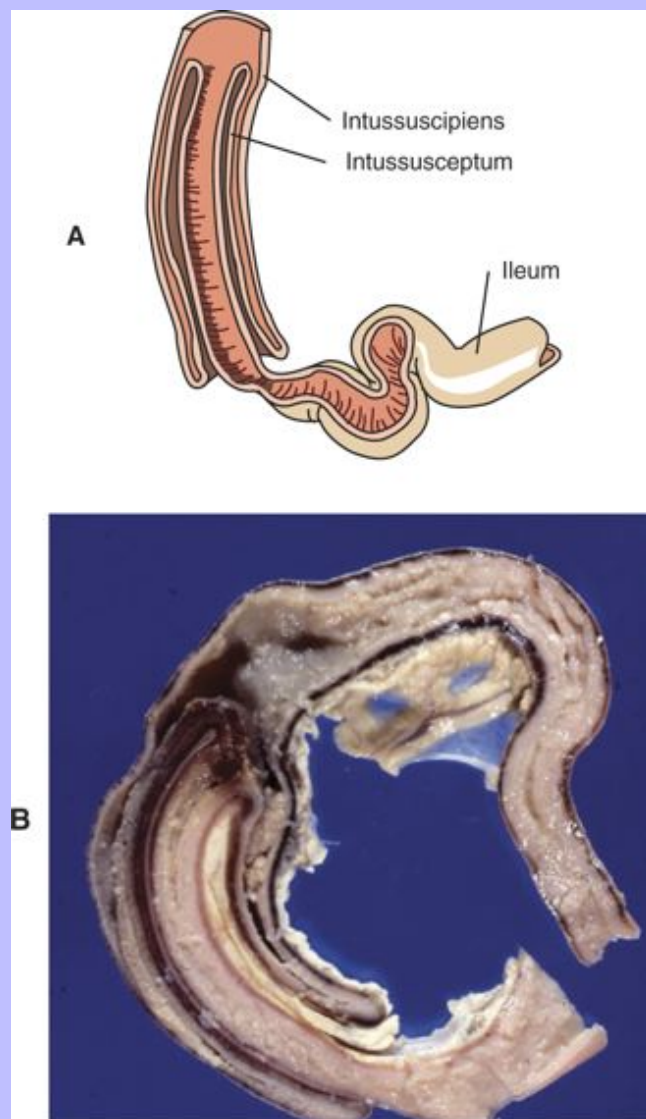

Fig. 7-109 **Ileocecal intussusception, ileum, horse.** The necrotic intussusciens is present in the lumen of the opened cecum. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-110 **Accordion-folded intestines.** **A**, Small intestine, cat. A linear foreign body (roast beef string) has caused the accordion-folded appearance of the small intestine (*lower*). Peristalsis of the intestine over the string, which is taut, in the intestinal lumen causes a sawing, abrasive effect and perforation of the intestine resulting in peritonitis, the white exudate seen on the serosal surfaces. **B**, Intussusception, intestine, pig. The accordion-folded intussusception (*left*) is contiguous with infarcted bowel, the result of vascular strangulation. (**A**, Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

350

7.2.9.7

### ILEUS

351

Paralytic ileus (adynamic ileus) is a nonmechanical hypomotility resulting in a functional obstruction of the bowel (pseudoobstruction). It can be due to paralysis of the bowel wall (generally the result of bowel manipulation at surgery), peritonitis from any cause, shock, severe pain, abnormal stimulation of splanchnic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

nerves, toxemia, electrolyte imbalances (especially hypokalemia), vitamin B-complex deficiency, uremia, tetanus, diabetes mellitus, or heavy-metal poisoning.

The gut is not paralyzed but because of continuous nerve discharge it becomes refractory, resulting in lack of tonic stimulation of the bowel musculature. In most cases of paralytic ileus, there are no gross lesions. It occurs in most animal species.

Grass sickness of equids in Europe is associated with gastrointestinal hypomotility and subsequent colic. Degenerative lesions of this idiopathic condition are present in the autonomic ganglia, suggesting it is an acquired dysautonomia. An occasional outbreak in equids is associated with the temporospatial occurrence of similar lesions in rabbits.

7.2.9.8

### INTESTINAL DISPLACEMENTS

Intestinal displacements include herniations that lead to incarcerations (fixation) of the displaced bowel and finally strangulations (interference with blood flow) of the incarcerated segment of intestine. Herniations are characterized as internal or external.

Internal herniations are displacements of intestine through a normal or pathologic foramen in the abdominal cavity. The most common of these displacements occurs in horses. They include herniation through the epiploic foramen and through mesenteric tears. The dorsal border of the epiploic foramen is formed by the caudate lobe of the liver and the caudal vena cava. The ventral boundary is the right lobe of the pancreas, the gastropancreatic ligament, and the portal vein. The cranial boundary is the hepatoduodenal ligament, and the caudal boundary is the junction of the pancreas and mesoduodenum. The epiploic cavity is only a potential space. It is proposed that the caudate lobe of the liver atrophies in older animals, enlarging the foramen and allowing loops of intestine to slip through and become incarcerated and strangulated ([Fig. 7-111](#)).

External hernias are formed when a hernial sac, formed by a pouch of parietal peritoneum, penetrates outside the abdominal cavity. Types of external herniation include umbilical, ventral, diaphragmatic ([Fig. 7-112](#)), hiatal, inguinal, scrotal ([Fig. 7-113](#)), and perineal. Perineal hernias are seen in old male dogs with prostate gland enlargement and obstipation. Some of these herniations (diaphragmatic, perineal) are more correctly termed eventrations (protrusion of the intestine through the abdominal wall or diaphragm) because they are not accompanied by a peritoneal pouch. Postoperative wound dehiscence of a ventral abdominal incision also causes eventration.

**Fig. 7-111 Herniation of small intestine through the epiploic foramen, abdomen, horse.** An enlarged epiploic foramen has allowed the small intestine to herniate through the foramen, become incarcerated, and then strangulated. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

**Fig. 7-112 Diaphragmatic hernia, abdomen, cat.** Traumatic rupture of the diaphragm has allowed intestines, stomach, and liver into the thoracic cavity, resulting in displacement and compression of the thoracic viscera and consequently compromise of cardiopulmonary function. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

It should be noted that umbilical hernias are generally caused by a defect in the abdominal wall and not by the chewing on the umbilical cord by the dam. Umbilical hernias may have a genetic basis, so it may be a

## Pathologic Basis of Veterinary Disease, 4th Edition

matter of some ethical concern whether to surgically repair these hernias in show and breeding animals. In calves, umbilical infections are also associated with an increased risk for hernia development.

Rectal prolapse may occur secondary to tenesmus or excessive postpartum straining (Fig. 7-114).

351

352

**Fig. 7-113 Scrotal hernia, scrotum, pig.** Loops of intestine within the scrotum entered through the inguinal canal to lie in the scrotal cavity and have displaced the testis (T) caudally. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.9

### VOLVULUS AND TORSION

A volvulus is a twisting of the intestine on its mesenteric axis. A torsion is a rotation of a tubular organ along its long axis. The latter is most common in the cecum of cattle and horses and occasionally of the abomasum of calves. Both volvulus and torsion result in vascular obstruction and ischemic injury. Infarction is a result of occlusion of the thin-walled mesenteric veins. Because the mesenteric arterial supply is anatomically more resistant to occlusion, blood is pumped into the twisted segment but cannot drain. Edema, congestion, hemorrhage, and eventual necrosis result (Figs. 7-115 and 7-116). It is probable that the mechanism of intestinal twisting is secondary to movement of the abdominal cavity (i.e., the intestine stays still and the horse rolls or otherwise moves around the static intestine).

**Fig. 7-115 Infarction, small intestine, horse.** Volvulus of the intestine has resulted in vascular compromise and infarction of several loops of bowel. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

At surgery or necropsy, the twisted segment of intestine is distended with gas and fluid and is discolored either dark red or black. There is usually a sharp line of demarcation between the affected and normal intestine. This line marks the site for surgical resection. A volvulus may result in a rotation of the intestine up to 720 degrees, either clockwise or counterclockwise on its mesenteric axis. Therefore surgical correction of a volvulus may be difficult and complex. It is very important to determine the viability of the bowel after reduction of a volvulus. The affected segment of intestine is often necrotic, congested, and hemorrhagic. Intestinal stasis and toxemia and/or bacteremia may result from bacterial overgrowth and anoxic bowel necrosis. Reperfusion injury may also occur. Toxemia and intestinal rupture may result in death.

Volvulus of the equine large intestine occurs most commonly in the left colon. In equids, the left ventral colon is an extension of the right ventral colon beginning at the sternal flexure. The left ventral colon doubles back on itself in the pelvic inlet to form the left dorsal colon. This pelvic flexure can be palpated

## Pathologic Basis of Veterinary Disease, 4th Edition

rectally. The left dorsal colon becomes the right dorsal colon at the diaphragmatic flexure. The diaphragmatic flexure lies cranial to the sternal flexure and usually contacts the ventral body wall. The left dorsal colon is sacculated with one taenia; the left ventral colon is sacculated with four taeniae. When twisting occurs, it is usually clockwise around the mesocolon and is thus a volvulus. Torsion of the large colon of mares accounts for half of their intestinal displacements in the peripartum period.

352

353

**Fig. 7-116 Torsion, large colon, horse. A,** Rotation of the colon on its long axis has resulted in severe colic with strangulation (*arrow*). Note the red to blue discoloration of the colon distal to the torsion caused by obstruction of venous blood flow. **B,** Note the sharp line of demarcation (point where the torsion occurred) between viable colon (to the right) and nonviable colon (to the left) caused by obstruction of venous blood flow. In this case, the torsion was not found at the time of necropsy; however, a torsion will commonly untwist itself (reduce itself) during transport of the dead animal to the postmortem room. The lesion is characteristic of a torsion. (**A**, Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University. **B**, Courtesy Dr. M.D. McCracken, College of Veterinary Medicine, University of Tennessee.)

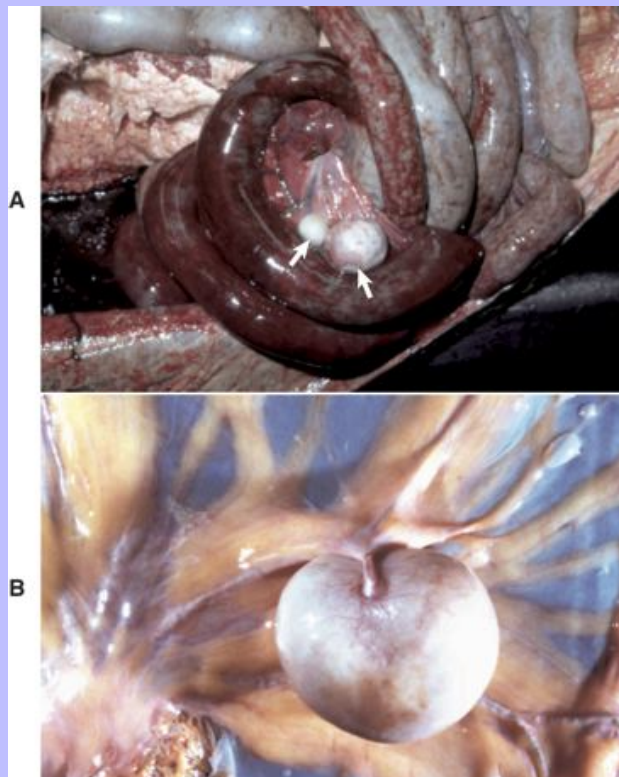

## Pathologic Basis of Veterinary Disease, 4th Edition

A peculiar type of intestinal strangulation occurs in horses in which lipomas, which are pedunculated, wrap around the intestinal mesentery or the bowel itself, causing ischemia, colic, and death (Fig. 7-117). However, most mesenteric lipomas are of no clinical consequence. Although rare, intestinal strangulation by pedunculated lipomas has been reported in the dog.

### 7.2.9.10 RENOSPLENIC ENTRAPMENT

Renosplenic entrapment of the large colon in horses is due to left dorsal displacement of the left dorsal colon or left ventral colon between the spleen and left body wall. Entrapment occurs over the renosplenic ligament that runs between the left kidney and the spleen. The cause of the displacement is unknown but could occur secondary to rolling behavior in horses or gaseous distention of the large colon. If not corrected either by rolling the horse or by surgery, intestinal rupture and death may result.

**Fig. 7-117 Pedunculated lipomas.** **A**, Intestinal strangulation by pedunculated lipomas, small intestine, horse. Two lipomas (*arrows*) have wrapped around the mesentery and strangled the bowel resulting in infarction. **B**, Mesentery, horse. Closer view of a pedunculated lipoma. ## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.9.11 MISCELLANEOUS DISEASES AND CONDITIONS

Cecal or large intestinal rupture occurs most commonly in postparturient mares (Fig. 7-118), but can also result from impaction and as a complication of anesthesia. The sites of rupture vary, and the mechanisms are unknown. Iatrogenic rectal tearing may occur secondary to rectal palpation (Fig. 7-119). The presence of blood on a rectal sleeve after palpation is cause for concern because peritonitis may be the result of penetration of the abdominal cavity.

Diverticula (singular, diverticulum) are epithelium-lined cavities that are derived from mucosal epithelium that extend through the muscularis mucosa, submucosa, and muscularis and often reach the serosa, where they sometimes rupture, causing peritonitis (Figs. 7-120 through 7-122). Muscular hypertrophy of the tunica muscularis associated with diverticulosis has been recorded in young Yorkshire pigs and in Romney Marsh and Hampshire sheep.

353

354

**Fig. 7-118 Fibrinous peritonitis, abdomen, horse.** The presence of fibrin and ingesta adherent to serosal surfaces indicates antemortem perforation or rupture of the intestine. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 7-119 Ulceration, rectum, horse.** Hemorrhage, ulcers, and tears in the rectum are often caused by inexperienced persons or overvigorous rectal palpation. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Muscular hypertrophy of the distal ileum is an idiopathic condition of horses and pigs. Although generally an incidental finding, hypertrophy of the tunica muscularis can lead to impaction and rupture of the ileum. The lesion in horses is sometimes segmental, affecting the ileum and variably the jejunum. Often the lesion is a sequela of muscular hypertrophy caused by a damaged or stenotic ileocecal valve. Muscular hypertrophy of equids may also affect the duodenum and jejunum in association with diverticula. Horses with muscular hypertrophy of the distal ileum may have mild colic, occasional diarrhea, and weight loss. Often muscular hypertrophy is asymptomatic. Muscular hypertrophy of the ileum in pigs generally occurs as an idiopathic, asymptomatic lesion. The lesion is suspected to be secondary to a functional obstruction of the ileocecal valve. Diverticulosis and/or intestinal rupture may result.

**Fig. 7-120 Diverticula, cecum, horse.** Diverticula are mucosal outpouchings into the subjacent smooth muscle layers of the colon. They are filled with ingesta and lined by intact mucosa. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-121 Diverticulum, colon, cow.** A diverticulum lined by superficial mucosa has penetrated through the submucosa to lie next to the muscularis. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Cats can have a severe hypertrophy of the inner, circular layer of the tunica muscularis of the ileum and sometimes the jejunum. In cats with hypereosinophilic syndrome, a disease characterized by intramural eosinophil infiltrates, hypertrophy of the gastric antrum and small intestinal musculature can occur. Muscular hypertrophy of the intestine and medial hyperplasia of the pulmonary arteries occur in cats given large oral doses of *Toxocara cati* larvae. These conditions are often accompanied by diarrhea and eosinophilic enteritis. Fibrosis of the lamina propria and hypertrophy of the inner layer of the tunica muscularis may result.

354

355

**Fig. 7-122 Mesodiverticulum, ileum, horse.** An intestinal mucosal outpouch has penetrated the wall of the intestine and extended into the mesentery (red nodule). (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

**Fig. 7-123 Hemomelasma ilei, ileum, horse.** Hemorrhagic and siderotic fibrovascular plaques on the antimesenteric serosa are attributed to strongyle larval migration (*Strongylus edentatus*). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Another unique lesion in the horse is hemomelasma ilei. These lesions are pink to black plaques that vary in length from several millimeters to many centimeters and can occur anywhere in the intestine but are generally limited to the ileum (Fig. 7-123). They are attributed to larval migrations of strongyles (usually *Strongylus edentatus*) and are located on the antimesenteric serosal surface. These fibrovascular serosal plaques are putatively formed in response to tissue damage caused by the migrating parasites. However, parasites have never been reported in the lesions and therefore the cause of hemomelasma ilei is unknown. They are generally of no clinical consequence, but can on occasion lead to intestinal strictures and intermittent colic.

Intestinal lipofuscinosis or leiomyometaplasia is also called “brown dog gut.” The discolored intestinal smooth muscle may occur in association with chronic enteritis and pancreatitis. Experimentally, leiomyometaplasia can be produced in dogs by vitamin E deficiency, in association with excess dietary lipids. The canine and human intestinal pigmentation is the result of vitamin E deficiency. The dietary requirement for vitamin E is proportional to the concentration of polyunsaturated fatty acids in the diet. Intestinal lipofuscinosis probably does not cause clinical signs but may be an indicator of a metabolic or nutritional disorder. In this condition, the intestinal serosa varies from tan to dark brown (Fig. 7-124). The stomach and large bowel are variously affected, as is the small intestine. Accumulation of brown, granular, acid-fast-staining lipofuscin in the perinuclear lysosomes of the leiomyocytes is characteristic of this condition.

**Fig. 7-124 Leiomyometaplasia, intestine, dog.** “Brown dog gut” is a rare condition caused by the accumulation of a brown pigment now known to be ceroid (formerly called lipofuscin) in the lysosomes of smooth muscle cells of the tunica muscularis. It is a dietary condition due to vitamin E deficiency. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

Amyloidosis occasionally is present in the intestines in association with systemic amyloid AA infiltrations in a variety of animal species.

Tiger striping is a nonspecific congestion of colonic ridges secondary to diarrhea and/or tenesmus ([Fig. 7-125](#)).

### 7.2.9.12 SMALL INTESTINAL INTOXICANTS

Because most toxins enter the body through ingestion, those that are irritants can cause contact lesions in the oral cavity, esophagus, stomach, and intestine. The lesions that result are generally those of hemorrhage and inflammation. In many cases of intoxication, induction of vomiting is contraindicated because what burns going down will also burn coming up. The numbers and types of chemicals and intoxicants animals are exposed to makes a listing of them a monumental undertaking. A few examples are phosphorus, arsenic, bracken fern (cattle), mercury, oak, copper, nitrate, thallium, and blister beetles. Blister beetles, a specific toxicity, are sometimes incorporated into crimped hay ([Fig. 7-126](#)). They contain a topical irritant called cantharidin. Lesions include sloughing of the epithelium of the stomach and enterocytes of the proximal small intestine ([Fig. 7-127](#)). In addition, cantharidin can cause hemorrhagic ulcers of the urinary bladder and myocardial necrosis.

355

356

Fig. 7-125 **Tiger striping, colon, dog.** Nonspecific congestion and hemorrhage of the colonic ridges is due to tenesmus and/or diarrhea. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-126 **Striped blister beetles.** Numerous species of blister beetles (*Epicauta* spp.) such as gray, black, and striped can be found throughout the United States. They contain a vesicant (blister-causing substance) that causes inflammation and blistering of mucosal surfaces when they are ingested. Usually, these beetles are trapped and crushed in crimped hay. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, University of Georgia; and Noah's Arkive, College of Veterinary Medicine, University of Georgia.)

**Fig. 7-127 Acute necrohemorrhagic enteritis, small intestine, horse.** The severe necrosis with sloughing of intestinal mucosa is the result of cantharidin, a toxin contained in ingested blister beetles. (Courtesy Dr. R. Panciera, School of Veterinary Medicine, Oklahoma State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Although not generally considered an intoxicant, corticosteroids cause colonic perforation in some treated dogs and can delay gastrointestinal healing. They do this by decreasing cell turnover, decreasing mucus production, and stimulating gastrin secretion, leading to increased acid production. NSAIDs can cause right dorsal colitis in equids. This colitis is characterized by necrosis, resulting in erosions and ulcers. Epithelial loss may be severe, with only regenerating, rounded islands of normal mucosa remaining. The massive edema of the denuded intestine causes rupture of the submucosa in an elongated diamondlike pattern. The mechanism of injury is direct by topical application (oral administration) and through inhibition of prostaglandin synthesis. Neutrophils play a role by increasing synthesis of tumor necrosis factor- $\alpha$ , leukotriene B<sub>4</sub>, and up-regulation of leukocyte adhesion molecules.

### 7.2.9.13 VASCULAR DISEASES OF THE INTESTINE

#### 7.2.9.13.1 Parasites

In horses, *Strongylus vulgaris* fourth-stage larvae are present in the wall of the cranial mesenteric artery, resulting in arteritis. So-called aneurysms (some with osseous metaplasia and bone marrow) and mural thromboses develop (Fig. 7-128). In many cases, even complete occlusion of the anterior mesenteric artery does not result in bowel infarction because collateral circulation will develop if the vascular occlusion develops slowly (Fig. 7-129). Therefore it is important to ascertain if the colonic arteries are thrombosed before assigning the cause of bowel death to *Strongylus vulgaris*. Severe colic and death often results from bowel infarction secondary to verminous arteritis and thrombosis.

356

357

Fig. 7-128 **Verminous arteritis, cranial mesenteric artery (C), horse.**

Chronic proliferative arteritis and mural thrombosis have resulted from the migration of *Strongylus vulgaris* fourth-stage larvae through and within the vessel wall at or near its origin from the aorta (A). The arteritis can lead to mural thrombosis, formation of aneurysms (*lower right*), arterial mineralization, and infarction of the bowel. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-129 **Infarcts, small intestine, horse.** Thromboemboli from sites of verminous arteritis in the cranial mesenteric artery will often lodge in end arteries of segments of the small intestine, resulting in sudden vascular occlusion and bowel infarction. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Third-stage larvae are ingested and molt to fourth-stage larvae in the small intestine. They then invade small arterioles on their way to the anterior mesenteric artery. It takes 3 to 4 months in this location until fifth-stage larvae are produced and migrate through the blood vessels to the cecocolonic subserosa. They may be walled off similarly to *Oesophagostomum* spp. in ruminants and pigs. In the lumen of the large intestine, adults develop. The entire cycle takes up to 6 months or more. Thus the prepatent period in foals is considerable, and by the time ova appear in the feces, significant vascular damage may have occurred. Modern and effective deworming regimens are quite effective and will hopefully succeed in making this disease of historic significance only.

### 7.2.9.14 LYMPHANGIECTASIA

Lymphangiectasia, or lacteal dilation, is the most commonly reported cause of protein-losing enteropathy in dogs. Clinical signs include diarrhea, steatorrhea, hypoproteinemia, and ascites (Fig. 7-130).

Lymphangiectasia can be due to a congenital developmental disorder of the lymphatic vessels, or it can be acquired secondary to lymph vessel obstruction caused by granulomatous or neoplastic diseases. An inherited cause is suspected in some canine breeds. A special case is lipogranulomatous lymphangiectasia of the dog, the name of which is descriptive of the lesions present. Most cases of acquired lymphangiectasia are idiopathic. Gross and microscopic lesions are those of lymphangiectasia and include a thickened intestinal mucosa with dilated lymphatics and lacteals (Figs. 7-131 and 7-132). There are variable increases in lymphocyte and plasma cell numbers in affected tissue.

### 7.2.9.15 DISEASES OF THE INTESTINAL EPITHELIUM

A number of diseases are characterized by colonization or destruction of the epithelial components of the intestinal mucosa. Although the disease-producing effects of pathogens are complex and multifactorial, a simplified understanding of the principal cell under attack is helpful in predicting disease outcome and managing treatment.

357

358

**Fig. 7-130 Ascites, abdomen, emaciation, dog, Doberman pinscher.** Protein-losing enteropathy, secondary to idiopathic intestinal lymphangiectasia resulted in hypoproteinemia and then ascites. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-131 Lymphangiectasia, jejunum, dog.** Intestinal villi are expanded by ectasia of the lymphatics (*raised white areas*). Lymphangiectasia can be a congenital developmental disorder of the lymphatic vessels, or it can be acquired secondary to lymph vessel obstruction caused by granulomatous or neoplastic diseases. **Fig. 7-132 Lymphangiectasia, jejunum, dog.** Lacteals are dilated, thus resulting in diminished lymph absorption by lacteals in the lamina propria and subsequent loss of protein (hypoproteinemia) and other nutrients into the intestinal lumen. H&E stain. (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

### 7.2.9.15.1 Diseases of the Absorptive Enterocytes

A number of agents have a tropism for the absorptive cells lining the intestinal villi. These agents include viruses such as rotavirus, enteric coronavirus, and the coronavirus of transmissible gastroenteritis of pigs. Intracellular bacteria and parasites can likewise invade and multiply in absorptive epithelial cells.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Examples include the agent of swine dysentery (*Brachyspira hyodysenteriae*), coccidia, and cryptosporidia.

Some pathogens with a tropism for absorptive lining cells of the intestine cause destruction of these cells. This results in loss of enterocytes and at least temporary villous atrophy. The loss of the absorptive-digestive villous enterocytes causes maldigestion, and malabsorption results. Furthermore, because ingesta and normal alimentary secretions are unabsorbed, they are degraded further and fermented in the intestine by bacteria, increasing the osmolality of intestinal contents, with a subsequent increase in the fluid content of the bowel.

Because the regenerative crypt cells are not attacked by pathogens with tropism for villous enterocytes, diseases with villous enterocyte damage are not necessarily fatal. The lost cells are replaced by the maturing cells migrating along the basement membrane from the crypt to the villus. The naked basement membrane contracts, causing villous atrophy. This contraction may be a function of the smooth muscle in the lamina propria. The functionally immature migrating crypt cells cover the villi. Often these immature cells become squamoid in an effort to cover the maximum area of basement membrane. However, if naked basement membranes contact each other, they will adhere, resulting not only in villous blunting but also villous fusion, preventing the reformation of normal villi.

### 7.2.9.15.2 Diseases of Undifferentiated Crypt Cells

Loss of the undifferentiated epithelial cells in the base of the crypts means loss of the cells capable of rapid mitosis, and thus regeneration of the epithelium is impaired. Therefore the clinical effect of crypt cell loss can be delayed for several days because the villi are initially still covered by enterocytes. This type of loss is more severe, and often fatal, compared with villous enterocyte loss. Agents that target the crypt cells are called radiomimetic because they mimic the effects of radiation on the rapidly dividing enterocytes. Examples of these agents include the parvoviruses of carnivores, BVD virus, rinderpest virus, and some mycotoxins such as vomitoxin.

### 7.2.9.15.3 Abnormalities of the Microvilli and Glycocalyx

Because the microvilli and glycocalyx on the villous enterocytes are largely responsible for the immense surface area and enzymes responsible for nutrient digestion and absorption, it follows that damage to either of these structures can result in intestinal malfunction and resultant diarrhea. A prime example of this is human lactose intolerance. Such persons lack lactase in the glycocalyx. Because of this lack, they are unable to digest lactose from dairy products. The lack of lactase results in failure of uptake, and the lactose is fermented by bacteria in the colon. This results in an osmotic drain of fluid into the gut with resultant diarrhea. Thus the malabsorption in this case is limited to a single substrate. Histologically the intestine is normal.

Some bacteria, such as attaching and effacing *Escherichia coli*, damage the microvilli by their attachment. This attachment disrupts enzyme systems housed in the microvilli and glycocalyx and causes diarrhea.

The antibiotic neomycin can similarly cause fragmentation of microvilli and destruction of the glycocalyx with resultant diarrhea. Cessation of neomycin therapy results in a return to normal structure and function.

358

359

### 7.2.9.15.4 Diseases in Which the Epithelial Targets Are Unknown or Nonspecific

In a number of enteric diseases, the targeted epithelial cell is unknown or nonspecific. Many of the pathogens causing these diseases are of importance in the young of food-producing animals. Enterotoxigenic *Escherichia coli* infection of neonatal pigs, calves, lambs, and human beings causes what is known as a secretory diarrhea. These bacteria are able to colonize the small intestinal enterocytes by way of their surface or pili antigens, which anchor them to the enterocytes. Different pili antigens adhere to glycoconjugate receptors on enterocytes in different regions of the small intestine. Thus these bacteria are not washed out by peristalsis. Because the enterocytes are not damaged, no lesions are observed, although microscopically the bacteria can be seen attached to the epithelial surface. The bacteria produce a toxin that causes enterocytes to secrete water and electrolytes. Although cAMP (cyclic adenosine monophosphate) and cGMP (cyclic guanosine monophosphate) mediate this process, the exact mechanism by which this secretion occurs is unknown. Some secretions, especially those of chloride ions, occur via the crypt cells. Intestinal secretion exceeds the ability of the colon to absorb the surplus fluid. The net result is diarrhea.

*Clostridium perfringens* type C is a pathogen of neonatal pigs, lambs, calves, and foals. Unlike the enterotoxigenic *Escherichia coli*, which produces a toxin affecting enterocytes, *Clostridium perfringens* produces a nonspecific cytotoxin. This toxin causes necrosis of villous absorptive cells, which then extends to the lamina propria and blood vessels. The result is massive and acute necrohemorrhagic enteritis.

### 7.2.9.15.5 Separation of Apical Junctional Complexes

Apical junctional complexes, also called tight junctions or zona occludens, join enterocytes to each other. Normally, these junctions are a barrier to macromolecular transepithelial transport. In certain parasitic diseases, such as ostertagiosis, these tight junctions are pathologically opened, allowing transport of macromolecules into the intestinal (abomasal) lumen. This opening of tight junctions is also important in allowing macromolecules, such as immunoglobulin, into the lumen where the parasites can be attacked.

### 7.2.9.16 DISEASE OF THE LAMINA PROPRIA

Lesions within the lamina propria can be infiltrative, necrotizing, or vascular, all of which can cause diarrhea even though the epithelium is not the primary cell type injured.

#### 7.2.9.16.1 Inflammation

Chronic injury of the lamina propria that results in dense cellular infiltration can cause diarrhea in a variety of ways, none of which are completely understood. These mechanisms include simple physical impairment of mucosal diffusion by space-occupying cells with resultant disruption of the overlying epithelium causing increased permeability. Examples of these diseases in domestic animals are canine histiocytic ulcerative colitis (boxer colitis), Johne's disease (paratuberculosis) of cattle, amyloidosis, and lymphoma.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 7.2.9.16.2 Necrotizing Processes

Primary necrotizing processes of the lamina propria generally involve necrosis of the GALT with extension to the overlying epithelium. Examples of diseases with these lesions include BVD of bovids and *Rhodococcus equi* infection of equids.

### 7.2.9.16.3 Vascular Changes and Lymphangiectasia

Vascular changes and dilation of lacteals are idiopathic or secondary to obstruction of flow. These lesions are seen most commonly as part of the syndrome resulting from space-occupying lesions of the lamina propria, such as occurs in Johne's disease and lymphoma. Endotoxemia that results in vascular damage and disseminated intravascular coagulopathy can cause thrombi in small vessels, and hemorrhage, necrosis, and ulceration of the intestine.

### 7.2.9.17 DISEASES DUE TO SPECIFIC PATHOGENS

A number of pathogens affect different animal species in similar ways. The mechanism of damage is similar among these animal species and pathogens. Therefore it is useful to discuss the diseases caused by these organisms across species. Specific diseases that do not have analogs in other species are described later in this chapter.

#### 7.2.9.17.1 Viral Diseases

##### 7.2.9.17.1.1 Group A rotavirus enteritis

Rotaviruses are ubiquitous pathogens present everywhere in the environment, including air and water. Each species of animal has its specific rotavirus, and although broad similarities exist in pathogenesis among viral infection of individual species, in general the viruses are not cross infective among species. These viruses are important pathogens. Human group A rotavirus, for example, kills a million children a year in the developing countries of the world. In all species, these viruses cause disease in association with other enteropathogens of neonates.

In calves, the disease is most important during the first week of life and in piglets in the first 7 weeks of life. These ages correspond to the reduction of colostral and milk-associated antirotavirus antibody titers that occur after weaning. Specific diagnosis of these diseases is difficult for a variety of reasons. The virus is ubiquitous and therefore can be isolated or detected in many animals, most of whom do not have clinical disease. Additionally, because the viruses are cytolytic, some animals with viral diarrhea can be negative for viruses because the cells harboring the virus have been shed previously in the feces.

Rotaviruses are about 70 nm in diameter and are trilayered. Only the complete triple-layered virion is infectious. Rotaviruses have double-stranded RNA at their core, and protein spikes project from the surface. The complete particle looks like a wheel, thus the appellation rotavirus. Piglets and calves with rotavirus disease have dehydration and yellow, watery diarrhea and are weak and depressed. Production of clinical disease is dependent on the amount of villous epithelium that is lost. This varies by host species. The epithelial cells over the upper two thirds of the affected villi of the proximal small intestine are infected first in those species that suffer with severe diarrhea from rotavirus infection (Fig.

359

360

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7-133). Sloughing of villous cells results in shortening and sometimes fusion of villi, if basement membranes are exposed (Fig. 7-134). Depending on the degree of enterocyte loss, recovery may be delayed or incomplete depending on the amount of absorptive surface that is permanently lost. Death, when it occurs, is generally associated with intercurrent infections with those organisms that also target villous epithelial cells, such as coronavirus, cryptosporidia, *Escherichia coli*, coccidia, and others.

**Fig. 7-133 Rotavirus enteritis, jejunum, piglet.** Infected enterocytes contain large amounts of viral antigen (*brown*). Note that infected enterocytes are those that cover the tips and upper sides of intestinal villi. Antirotavirus immunoperoxidase stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-134 **Rotavirus enteritis, jejunum, piglet.** There is notable blunting and fusion of intestinal villi secondary to virus-induced cytolysis of enterocytes covering the tips and sides of intestinal villi. H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.17.1.2

### Coronavirus enteritis

Coronaviruses responsible for calfhood enteritis (at 100 to 120 nm) are larger than a rotavirus. Their genetic core is single-stranded RNA. Peplomers project from the surface, resulting in the appearance of a corona, such as created by the sun; hence the appellation coronavirus. The clinical course of the disease, histologic lesions, mechanism of diarrhea production, and age of affected calves is very similar to that of rotavirus enteritis although somewhat prolonged. Virus infection is more virulent than in rotavirus enteritis and death more common. Colitis occurs in addition to small intestinal involvement, but the principal disease signs and pathogenicity are related to the small intestinal lesions. In the colon, similar to the small intestine, enterocytes when lost are initially replaced by less mature and often squamoid cells. Unlike in rotavirus enteritis, crypt lumens contain cell debris and crypt cells may be focally hyperplastic. The lamina propria and draining lymph nodes often contain increased numbers of inflammatory cells. A hemorrhagic form of the disease with extensive colitis has been reported.

Although generally a mild and self-limiting disease of neonates, feline enteric coronavirus has been associated with fatal enteritis in a series of cats. Lesions consist of degeneration and loss of enterocytes from jejunal villous tips. Cats 2 months to 7 years old are affected.

360

361

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.17.1.3

### Adenovirus enteritis

Adenoviral infection occurs in cattle, sheep, pigs, goats, Spanish ibex, cervids, horses, and inland bearded dragons. Each species-specific virus causes inapparent respiratory disease and under some circumstances clinical enteric disease. Other organs may also be affected, such as liver and kidneys. Endothelial cells are often affected. In Arabian horses and Arabian crossbreeds, adenovirus enteritis occurs in horses with combined immunodeficiency (CID). Adenovirus is transmitted by aerosols, feces, and fomites. When enteritis is produced, characteristic basophilic to amphophilic intranuclear inclusion bodies are present in villous enterocytes, usually in young animals that are immunosuppressed. Endothelial cells also are affected and have similar inclusions. Loss of enterocytes results in villous blunting and fusion. In general, adenovirus infection is subclinical.

7.2.9.17.2

### Bacterial Diseases

7.2.9.17.2.1

### *Escherichia coli* diseases (colibacillosis)

Coliform bacteria arrive early among the normal flora that colonizes the intestinal tract of virtually all animals. Young animals are at highest risk for coliform diarrhea, especially pigs and calves. There is interplay of many intrinsic and extrinsic factors that act together to determine if disease will be produced by infection. Some of the factors are the genetic make-up of the host animals, the passive transfer of specific antibodies in the colostrums, the constant bathing of the intestine with milk-associated antibodies from nursing, environmental contamination, and the nutritional plane of the host. Environmental stressors predisposing to disease production include temperature extremes, crowding, and intercurrent infections with rotavirus, coronavirus, cryptosporidia, coccidia, and others. The development of unique serotypes of *Escherichia coli* may cause problems in individual environments. In the past, autogenous vaccines, made to order for these environments, have been reasonably effective in controlling some disease outbreaks. Probiotics containing several *Escherichia coli* types and/or *Lactobacillus* spp. have shown promise as a preventative in calves. Lytic phages have also been promising in eliminating infection.

There are a variety of classification schemes for the *Escherichia coli* enteritides. They include enterotoxigenic, septicemic, edema disease, postweaning, enteroinvasive, and attaching and effacing.

*Escherichia coli* attach to cells by a variety of pili or fimbriae (Fig. 7-135). Enterotoxigenic *Escherichia coli* may have fimbrial antigens F4 (K88), 5 (K99), 6 (987P), 18, or 41 and may also produce up to three enterotoxins (STa, STb, LT) and shigatoxins. Fimbrial and nonfimbrial adhesions such as AIDA-1 may also be present. *Escherichia coli*-induced diseases are grouped into several clinical syndromes.

Fig. 7-135 **Colibacillosis, intestine, piglet.** *Escherichia coli* pili (arrows) are attached to enterocytes. TEM. Uranyl acetate and lead citrate stain. (Courtesy Dr. R. Isaacson, College of Veterinary Medicine, University of Minnesota.)

Many *Escherichia coli* produce verotoxins (VTEC) important in disease pathogenesis. More than 200 serotypes of VTEC have been isolated from cattle alone. Diagnosis of toxin-producing *Escherichia coli* is by selective culture properties of the bacteria, immunomagnetic separation, and other monoclonal-based immunoassays for the Vero-Shiga toxins. More recent developments are the use of real-time polymerase chain reaction (PCR) to detect pathogenic gene sequences.

### 7.2.9.17.2.1.1

#### Enterotoxigenic colibacillosis.

*Enterotoxigenic colibacillosis* occurs most often in animals 2 days to 3 weeks of age. Calves and piglets are most often affected. Why enterotoxigenic colibacillosis is a disease of neonates is not well understood. Some speculation is that enteric bacterial colonization is a function of gastric acidity and that the low pH of the stomach of postneonatal animals kills the bacteria.

The diarrhea that occurs is a function of bacterial endotoxin-induced sodium and chloride secretion into the intestinal lumen. Water is drawn into the intestine to normalize the resultant NaCl. Thus the diarrhea is termed secretory. Diarrhea is voluminous, yellow to white, and watery to pasty. Affected animals are dehydrated, with a “tucked up” abdomen. Subsequent to dehydration, the eyes of affected animals may be recessed deeply into their sockets (sunken eyeballs). Animals that die of enterotoxigenic *Escherichia coli* infection are often emaciated and have diarrheic feces pasted around their perineum. At necropsy, the small intestine is dilated, flaccid, and filled with translucent, yellow fluid and sometimes gas. Chyle is present in the mesenteric lymphatic vessels similar to animals without enteric disease, indicating that unlike the malabsorptive diseases of the small intestine, absorption proceeds normally in cases of enterotoxigenic colibacillosis. Microscopically the intestine is

361

362

## Pathologic Basis of Veterinary Disease, 4th Edition

also normal. Diagnosis can be made by light microscopic examination in freshly dead animals by noting the presence of bacteria lining the luminal surface of the enterocytes (Fig. 7-136).

**Fig. 7-136 Enterotoxic colibacillosis, jejunum, piglet.** Mats (arrows) of *Escherichia coli* are attached to the microvillous surface of the enterocytes. H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.17.2.1.2

### Septicemic colibacillosis.

Septicemic colibacillosis is a disease of newborn calves, lambs, and occasionally foals that have not received sufficient colostrum to develop immunity. Although the lesions produced are generally those of septicemia, similar to those caused by other organisms, infection can localize in the intestine, causing enteritis. Diagnosis is generally made by finding fibrin in any location in the body, such as the eye, joints, abdomen, heart sac, or chest. The bacteria gain entry to the body through the respiratory system, oral cavity, or umbilicus. Fibrinous arthritis, ophthalmitis, serositis, meningitis, (polyserositis) and white-spotted kidneys (cortical abscesses) characterize the septicemia. Mixed bacterial infections often occur with enterotoxigenic *Escherichia coli*.

7.2.9.17.2.1.3

### Edema disease.

Edema disease, also known as enterotoxemic colibacillosis, is an *Escherichia coli* infection that is specific for pigs. Edema disease is caused by a bacterial enterotoxin (verotoxin) produced in the small intestine and spread hematogenously via induction of IL-8. This interleukin attracts neutrophils that carry the toxin throughout the body. It is generally a disease of pigs 6 to 14 weeks of age and is usually associated with dietary changes at weaning. It is often noted that the best pigs in a group are the ones affected. Edema disease is characterized by neurologic signs including incoordination, poor balance, weakness, tremors, and convulsions.

Hemolytic *Escherichia coli* proliferates in the small intestine subsequent to dietary changes and produces a heat-labile exotoxin called the edema disease principle. This systemic toxin (angiotoxin) causes generalized vascular endothelial injury of arterioles and arteries, resulting in fluid loss and edema. The edema can be found anywhere but is most characteristic in the gastric submucosa,

## Pathologic Basis of Veterinary Disease, 4th Edition

eyelids (Fig. 7-137), forehead, gallbladder, and mesentery of the spiral colon (Fig. 7-138). In the brain, arterial damage causes focal malacia in the medulla, thalamus, and basal ganglia. These nervous tissue lesions are collectively known as focal symmetric encephalomalacia or swine cerebral angiopathy and are responsible for the variety of clinical signs. Death is due to an endotoxic shocklike syndrome. Some animals suffer from a Schwartzman-like bilateral renal cortical necrosis. Morbidity within a herd is approximately 35% and all affected animals die.

**Fig. 7-137 Edema disease, head, pig.** The skin of the eyelids, snout, and submandibular area are edematous due to production of angiotoxin by *Escherichia coli*, which increases the permeability of capillaries. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.17.2.1.4

### Postweaning colibacillosis.

Postweaning colibacillosis is another specific disease of pigs caused by a hemolytic *Escherichia coli*. The disease appears identical to enterotoxigenic colibacillosis of the neonate in that it produces a secretory diarrhea and therefore no lesions. It is a distinct strain of *Escherichia coli*, however, and is associated with feed and management changes at weaning.

7.2.9.17.2.1.5

### Enteroinvasive colibacillosis.

This disease is described in human beings, laboratory animals, and occasionally cattle and pigs. It has not been reported as a field problem in livestock. The pathogenesis of the disease is similar to that of other invasive bacteria such as *Salmonella* spp. In human beings, the colon is affected. A Shiga toxin gene, a locus for enterocyte effacement, and a plasmid encoding for hemolysin are produced by *Escherichia coli*, which results in hemorrhagic colitis and sometimes the hemolytic-uremic syndrome. These strains are also called VTEC or verotoxin *Escherichia coli* strains based on the Vero (African green monkey kidney) cell line on which the bacteria are sometimes grown. Outbreaks of enteroinvasive colibacillosis in human beings are often food-borne illnesses. These organisms are pathogenic because of their acid resistance and ability to survive the acid environment of the stomach. Shiga toxin-producing enterohemorrhagic *Escherichia coli* O157:H7 rarely causes naturally occurring disease in domestic livestock but often contaminates ground beef. Surveys have indicated that O157:H7 *Escherichia coli*'s seroprevalence in dairy herds is 38.5%, with an individual cow prevalence of 6.5%, and is most often isolated from the skin surface. This finding is an important reason not to eat undercooked ground beef. Steaks are a different matter because bacterial contamination is only a surface phenomenon and bacteria are killed by surface searing of meat. Experimentally, calves may have necrohemorrhagic or mucohemorrhagic diarrhea develop. Human disease can be serious, resulting in hemorrhagic colitis, thrombocytopenic purpura, and the hemolytic uremic syndrome. Deer, sheep, cattle, horses, dogs, and rabbits, including laboratory rabbits, may be carriers. Stable flies and fecal contamination of a variety of substances may create fomites.

7.2.9.17.2.1.6

### Attaching and effacing *Escherichia coli*.

This disease has been infrequently reported in rabbits, calves, pigs, lambs, dogs, and human beings. The actual incidence of this disease in domestic animals is unknown. Lesions are characterized by *Escherichia coli* attachment to the microvillous border of enterocytes and gallbladder epithelium via cups and pedestals (Fig. 7-139). Intimin, a bacterial outer membrane protein, facilitates bacterial attachment to the host cell's membrane, resulting in attachment and effacement. Gross lesions are not present except that the intestine is dilated and fluid-filled. Colonization of the epithelium by attaching and effacing *Escherichia coli* is relatively common; disease occurs most often in association with other enteropathogens of calves of this age, namely rotavirus, *Cryptosporidium parvum*, enterotoxigenic *Escherichia coli*, coronavirus, BVD, and coccidia. In contrast to enterotoxigenic *Escherichia coli* infection, in attaching and effacing *Escherichia coli* infection the brush border of the enterocytes is disrupted and can be seen on select enterocytes in hematoxylin and eosin (H&E) stained tissue sections. Microvillous disruption results in loss of the glycocalyx digestive enzymes, resulting in maldigestion, malabsorption, and diarrhea.

Fig. 7-139 **Attaching and effacing *Escherichia coli*, intestine, rabbit.** Bacterial rods have attached to and effaced the microvillous border of enterocytes. TEM. Uranyl acetate and lead citrate stain. (From Thulin, J, Kuhlenschmidt M, Gelberg H: Lab Invest 54:719-731, 1991.)

7.2.9.17.2.1.7

### Mucoid enteropathy.

This subacute and fatal disease of young rabbits is characterized by copious quantities of mucus in the feces concurrent with impaction of the cecum and sometimes the sacculated colon. Although the cause is unknown, coliform bacteria are suspect.

7.2.9.17.2.2

### Salmonellosis

*Salmonella* spp. are enteroinvasive bacteria. All known species of *Salmonella* are pathogenic, and it is an important zoonosis and nosocomial infection. Salmonellosis is a significant cause of acute and chronic diarrhea and death in numerous animal species and in human beings. *Salmonella typhimurium* is the second most common food-borne pathogen in human beings. In veterinary medicine, salmonellosis can occur epizootically, enzootically, or sporadically. The species most often isolated from diseased animals include *Salmonella typhimurium*, *Salmonella enteritidis*, *Salmonella dublin*, *Salmonella choleraesuis*, and *Salmonella typhosa*.

363

364

The salmonellas are gram-negative, aerobic to facultatively anaerobic and motile. They survive and multiply within phagocytic cells, resulting in granulomatous inflammation. The form of salmonellosis that occurs—septicemic, acute enteric, or chronic enteric—depends on the challenge dosage of the bacterium, previous exposure to the bacterium, and stress factors, such as overcrowding, transport, cold temperatures, feed changes, pregnancy, parturition, surgery, anesthesia, and antibiotic administration. Some recovered animals become carriers and shed the organism in their feces, particularly after stress.

## Pathologic Basis of Veterinary Disease, 4th Edition

This may make diagnosis by culture difficult because carriers may not be ill. Conversely, antibiotic treatment of ill animals may create false-negative bacterial cultures. Although dogs and cats rarely get clinical salmonellosis, 10% are carriers and can infect their human companions. Recently, it has been documented that fatal salmonellosis may occur in cats in association with homemade, raw-meat diets.

The most common route of bacterial entry is fecal-oral. Effective hand washing is thus of paramount importance for food handlers. Besides being present in contaminated feed, water, and aerosols, flies and fomites can transmit salmonella. Transplacental infection may also occur. After ingestion, salmonella may colonize regional lymphoid tissue in the oral cavity and gut. Some species are enteroinvasive.

*Salmonella enterica* serovars *choleraesuis* and *typhimurium* in pigs have been shown to adhere to apical membranes of M cells, enterocytes, goblet cells, and sites of cellular extrusion. Salmonellas produce disease via enterotoxins, cytotoxins (verotoxins), and endotoxins. Experimental infections of calves with *Salmonella typhimurium* demonstrate up-regulation of CXC chemokines (IL-8, GRO- $\alpha$  and GCP2), IL-1- $\beta$ , IL-1R- $\alpha$  and IL-4 associated with a neutrophilic influx. Once in contact with macrophages of the lamina propria or Peyer's patches, the organisms are phagocytosed and transported to regional lymph nodes or by way of the portal circulation to the liver. The organisms colonize the small intestine, colon, mesenteric lymph nodes, and gallbladder, which may serve as reservoirs in carrier animals. Salmonellosis infects the young more frequently; the young are more severely affected than are adults; and the young are more likely to succumb to septicemia.

7.2.9.17.2.2.1

### Peracute *salmonella* septicemia.

Peracute *Salmonella* septicemia is a disease of calves, foals, and pigs. Young animals are generally at greater risk than older animals, although the reasons for this difference are not understood. In foals, the feces of affected animals are typically green. The species of *Salmonella* most often involved in septicemic salmonellosis is *Salmonella choleraesuis*. Gross lesions of animals dying of peracute *Salmonella* septicemia are minimal and are due to fibrinoid necrosis of blood vessels. Necrosis of blood vessels causes a widespread petechiation and a blue discoloration (cyanosis) of the extremities and ventrum of white pigs. Fibrinous polyserositis may be present. Peracute *Salmonella* septicemia is usually fatal in animals 1 to 6 months of age. Death is usually attributable to disseminated intravascular coagulopathy secondary to the generalized Shwartzman reaction.

7.2.9.17.2.2.2

### Acute enteric salmonellosis.

This disease is caused most frequently by *Salmonella typhimurium* and occurs in cattle, pigs, and horses. Carnivores are rarely affected. Characteristic of the disease is diffuse catarrhal enteritis with diffuse fibrinonecrotic ileotyphlocolitis. Intestinal contents are malodorous and contain mucus, fibrin, and occasionally blood. The feces have a septic tank odor. Multiple foci of hepatocellular necrosis and hyperplasia of Kupffer cells (paratyphoid nodules), when present, are characteristic of acute enteric salmonellosis. Lymphadenopathy is usually present. Fibrinous cholecystitis at necropsy is pathognomonic for acute enteric salmonellosis in calves.

7.2.9.17.2.2.3

### Chronic enteric salmonellosis.

This disease occurs in pigs, cattle, and horses. Lesions are seen principally in pigs that have discrete foci of necrosis and ulceration, principally in the cecum and colon. These are termed button ulcers

364

## Pathologic Basis of Veterinary Disease, 4th Edition

(Figs. 7-140 and 7-141). Additionally, because salmonellosis causes vascular thrombosis and pigs have poor or no collateral blood supply to the rectum (cranial hemorrhoidal artery), in affected animals rectal strictures develop, with resultant abdominal distention secondary to fecal retention.

365

**Fig. 7-140 Button ulcers (arrows), colon, pig.** Multiple foci of necrosis (infarcts) due to chronic enteric salmonellas are termed “button ulcers” and are pathognomonic for this disease in North America and in other areas where hog cholera has been eradicated. The morphology of this lesion is attributable to bacterial toxin-induced vasculitis and thrombosis of blood vessels in the lamina propria and submucosa resulting in focal intestinal infarcts. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-141 **Chronic enteric salmonellosis, colon, pig.** Multiple foci of mucosal necrosis (*arrow*) are termed “button ulcers” and are pathognomonic for chronic enteric salmonellosis in hog cholera-free areas. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

7.2.9.17.2.3

### Clostridial enteritis

Many diseases that affect animals and human beings are caused by clostridial organisms. This discussion is limited to those clostridia that produce diarrheal disease. All clostridial enteritides produce enterotoxemias.

*Clostridium perfringens* is a gram-positive, anaerobic bacillus that normally inhabits the gastrointestinal tract and is ubiquitously present in the environment. It is the most important cause of clostridial enteritis in domestic animals. At least 17 exotoxins have been described, but only 4 are believed to be involved in the pathogenesis of disease. These spore-forming bacilli produce their toxins when circumstances provide them with an excess of growth that requires nutrients in an anaerobic environment. The four major toxins— $\alpha$ ,  $\beta$ ,  $\epsilon$ , and  $\iota$ —are used to classify the toxigenic types of *Clostridium perfringens* into five major groupings: A through E. The toxins are protein exotoxins, some of which are proenzymes. Some of the toxins have enzymatic activity. *Clostridium perfringens* type A produces the  $\alpha$ -toxin responsible for necrotic enteritis of birds, enterotoxemia of calves and lambs, necrotizing enterocolitis of piglets, canine hemorrhagic enteritis, and possibly equine colitis. Type B produces  $\alpha$ -,  $\beta$ -, and  $\epsilon$ -toxins and the diseases lamb dysentery, hemorrhagic enteritis of neonatal calves and foals, and hemorrhagic enterotoxemia of sheep. Type C produces  $\alpha$ - and  $\beta$ -toxins and necrotic enteritis of birds, hemorrhagic enterotoxemia of neonatal farm animal species, and struck of sheep. Type D produces  $\alpha$ - and  $\epsilon$ -toxins and pulpy kidney disease of lambs and enterocolitis of goats of all ages. Type E produces  $\alpha$ - and  $\iota$ -toxins and enteritis of lagomorphs and possibly enterotoxemia in calves and lambs.

Enterotoxigenic strains of *Clostridium perfringens*, particularly type A, are responsible for clostridial food poisoning. This generally occurs when cooked foods are improperly stored, and spores that survive the cooking environment germinate and produce enterotoxin.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.17.2.3.1

### Enterotoxemia.

Enterotoxemia is produced by one of the five *Clostridium perfringens* types described previously. Type D occurs most often. Clostridial enterotoxemia most often affects the better-fleshed animals within a group. Outbreaks often follow an abrupt change in the amount or quality of feed such as occurs in an animal being “finished” for sale or slaughter. In foals, enterotoxemia has been associated with feeding materials rich in carbohydrates and proteins. This diet leads to a change in the intestinal microbial balance. *Clostridium perfringens* proliferates and produces abundant toxin. Clinical signs may be absent before death or may include diarrhea, sometimes with blood. Glycosuria occurs only in lambs with enterotoxemia and is a helpful feature in preliminary necropsy diagnosis.

The small intestine, the target organ of clostridial enterotoxemia, typically has serosal and mucosal petechiae, ecchymoses, and paintbrush or diffuse hemorrhage similar in appearance to those of intestinal strangulation. The intestines are atonic and dilated. Emphysematous enteritis is variably present, as is coagulative necrosis of skeletal musculature. Congestive splenomegaly is present. Upon exposure to enterotoxin, villous tip enterocytes and midvillous enterocytes degenerate and are sloughed into the intestinal lumen, leaving denuded basement membranes. The exposed basement membranes allow fluid leakage and attract leukocytes into the lamina propria. Death is usually rapid.

7.2.9.17.2.3.2

### *Clostridium perfringens* type A.

*Clostridium perfringens* type A is the most frequently occurring clostridium in mammals and birds. It is also the most common clostridium found in the environment. *Clostridium perfringens* type A produces enteric disease in a great variety of animals. These diarrheal diseases are generally mild with minimal damage noted in the intestinal mucosa. In addition to enteritis, infection produces gas gangrene and other anaerobic wound infections. In the western United States, it causes hemorrhagic abomasitis in young ruminants, often accompanied by severe diarrhea. In the Pacific Northwest, principally in Washington and Oregon, a condition called yellow lamb disease is associated with *Clostridium perfringens* type A. Death is rapid and accompanied by clinical and pathologic signs of red cell lysis, hence the yellow discoloration of the carcass.

365

7.2.9.17.2.3.3

### *Clostridium perfringens* type B.

*Clostridium perfringens* type B is the cause of lamb dysentery. This is generally a disease of very young lambs, although older animals may be affected in prolonged disease outbreaks. Unexpected death is usual, but occasionally there is an antecedent anorexia and abdominal pain with or without severe bloody diarrhea. Other young ruminants and foals may also be affected. This disease occurs sporadically in the United States but is more common in Europe, South Africa, and the Middle East.

366

7.2.9.17.2.3.4

### *Clostridium perfringens* type C.

Enterotoxic hemorrhagic enteritis affects calves, lambs, and foals during the first few days of life and piglets during the first 8 hours of life. Clinical signs vary from none to bloody diarrhea. When piglets are affected, the whole litter dies. Lesions at necropsy include hemorrhagic or necrotizing enteritis of the small intestines, sometimes with gas in the lumen and within the walls of the intestine

## Pathologic Basis of Veterinary Disease, 4th Edition

(Figs. 7-142 and 7-143). Struck is a disease affecting adult sheep, goats, and feedlot cattle in winter and early spring. Also caused by *Clostridium perfringens* type C, it is characterized by hemorrhagic enteritis with ulceration, ascites, and peritonitis.

7.2.9.17.2.3.5

### Clostridium perfringens type D.

This bacterium affects fattening sheep, goats, and calves. The disease is diet-related and associated with grain overload or “overeating disease.” The sudden change in diet promotes growth of organisms in the small intestine. The disease is often characterized by unexpected death sometimes preceded by central nervous system signs or “blind staggers.” Endothelial cell damage is produced by a bacterial toxin (angiotoxin). This lesion can result in bilateral symmetric encephalomalacia, which is similar in its regional distribution to edema disease of pigs (swine cerebral angiopathy). Lesions of *Clostridium perfringens* type D infection are multisystem hemorrhages, particularly of serosal surfaces. Pericardial effusion is present along with mild gastroenteritis. The angiotoxin produces “pulpy kidney disease” of sheep.

**Fig. 7-142 Enterotoxemia, small intestine, pig.** The entire small intestinal mucosa is hemorrhagic. Necrosis can extend through the muscularis mucosa and is caused by toxins of the *Clostridium perfringens* type C group acting directly on the intestinal mucosa in the intestinal lumen. The entire litter of piglets was affected. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-143 **Clostridial enteritis, small intestine, pig.** Nonspecific necrotizing enteritis results from the toxins produced by *Clostridium perfringens* type C. H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.17.2.3.6

### **Clostridium perfringens type E.**

Case reports of necrohemorrhagic diarrhea associated with *Clostridium perfringens* type E infection are poorly documented. It is safest to state that *Clostridium perfringens* type E may rarely cause enterotoxemia of lambs, calves, and rabbits.

7.2.9.17.2.3.7

### **Peracute hemorrhagic gastroenteritis of dogs.**

Known as canine hemorrhagic gastroenteritis, the cause of this disease is undiscovered, but is considered likely a result of infection with *Clostridium perfringens* type E. The disease most often occurs in dogs of toy and miniature breeds younger than 2 years. Blood is observed at the anus before death. As the name of the disease denotes, there is hemorrhagic necrosis of the gastrointestinal mucosa anywhere from the stomach caudally. Numerous clostridial organisms are present in the intestinal debris but are not attached to intact mucosa. Unlike parvoviral enteritis in which crypts are preferentially destroyed, in hemorrhagic gastroenteritis the crypts are spared.

7.2.9.17.2.3.8

### **Lincomycin or antibiotic enteritis.**

This enteritis is associated with antibiotic administration and is seen most commonly in rabbits and horses; both are cecal fermenters. It has been suggested, but not proven, that antibiotic administration causes death of normal enteric flora, which allows overgrowth of *Clostridium perfringens* type A. Clinical signs and gross and microscopic lesions are similar to those observed in animals with *Clostridium* spp. enteritis, but bacterial organisms are often lacking.

366

367

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.17.2.3.9

### *Clostridium piliformis*.

Commonly called Tyzzer's disease, *Clostridium piliformis* infects multiple mammalian species. Although pathogen entry is usually via the intestine, the principal target is the liver, but lesions also occur in the intestine and heart. Intestinal involvement is variable and most common in rodents and rabbits. Colitis occurs in some cats. The enteric manifestations of Tyzzer's disease are generally in the distal small intestine, particularly the ileum. Mucosal necrosis and edema extend into the muscularis. Definitive diagnosis is made by finding the causative bacillus (best done with silver stains, such as Dieterle's or Steiner's) in the characteristic hepatic or intestinal lesions (Fig. 7-144). The target organs of *Clostridium piliformis* vary among affected animals.

7.2.9.17.2.3.10

### *Clostridium difficile*.

*Clostridium difficile* spores are common in the environment and in the intestinal tract of many mammals. They cause pseudomembranous colitis in primates including human beings, hemorrhagic necrotizing enterocolitis in foals, necrotizing typhlocolitis in horses (colitis X) and possibly cats, and enteritis in a variety of laboratory animals. *Clostridium difficile* also affects suckling pigs in outbreaks characterized by mesocolonic edema and typhlocolitis. Dogs, especially those hospitalized, may also shed the organism. *Clostridium difficile*'s disease producing ability in the dog is not understood, but its zoonotic potential may be important. The induction of disease by *Clostridium difficile* is likely dose-related, but the reasons for bacterial overgrowth, apart from those caused by oral antibiotic administration, are not understood. The lesions are similar to those produced by *Clostridium perfringens* infection.

**Fig. 7-144 Tyzzer's disease, intestine, foal.** Criss-crossed bacilli resembling Chinese characters or pickup sticks are diagnostic of infection with *Clostridium piliformis*. Warthin-Starry stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.17.2.3.11

### Clostridium spiroforme.

*Clostridium spiroforme* causes enterotoxemia in lagomorphs and rodents. The bacterium is semicircular in vivo and has a coiled appearance in vitro when bacteria are joined end to end. In the rabbit, weaning and/or antibiotic treatment with a concomitant change in cecal flora precede diarrhea and death. Lesions include a dilated cecum with liquid contents. As is the case with other clostridia, the cause is confirmed by mouse lethality studies or Vero cell cytotoxicity studies; the appropriate toxin is isolated from intestinal contents soon after death of the animal.

7.2.9.17.2.3.12

### Clostridium colinum.

Also known as quail disease, this ulcerative colitis is restricted to gallinaceous birds. The disease occurs in birds secondary to stress that is often a result of intercurrent infections. Classically, there is hemorrhagic enteritis of the small intestine often accompanied by necroulcerative enterotyphilitis. Necrohemorrhagic hepatosplenitis is often present. Death is rapid and losses are high, especially in quail.

7.2.9.17.2.4

### Campylobacteriosis(*Lawsonia*)

*Campylobacter* spp. are the cause of a proliferative segmental enteropathy in a variety of species, including human beings. *Campylobacter* are curved, gram-negative, motile, obligate intracellular bacteria that cannot be grown on artificial media. 16S ribosomal DNA of organisms from lesions shows a close resemblance to that of *Lawsonia intracellularis* of pigs, and isolates can cross-infect among species. Lesions of proliferative enteropathy have been reported in pigs, dogs, horses, sheep, rabbits, guinea pigs, hamsters, rats, ferrets, foxes, cervids, monkeys, ostriches, and emus. In the dog, the majority of cases occur in puppies younger than 3 months. Clinically, diarrhea is of 5 to 15 days' duration. The diarrhea is mucoid or watery, with or without blood, and accompanied by partial anorexia, vomiting, and a slight fever. Lesions consist of surface erosions and proliferation of cryptal enterocytes with the presence of bacteria in the apical cytoplasm of affected cells. Diagnosis depends on characteristic histopathologic findings of crypt cell proliferation and by the presence of comma-shaped bacteria in the intestinal crypt epithelial cytoplasm. *Campylobacter* infections from poultry are an important issue in food safety and thus an important emerging zoonotic disease.

7.2.9.17.2.5

### Mycobacterial enteritis

7.2.9.17.2.5.1

### Intestinal mycobacteriosis.

Intestinal tuberculosis, caused by *Mycobacterium tuberculosis* and *Mycobacterium bovis*, is an uncommon disease in cattle, nursing calves, nonhuman primates, and human beings. Although historically associated with drinking unpasteurized milk, more recently intestinal tuberculosis is an important AIDS-associated disease in human beings. The bacteria are ingested and then taken up by the M cells of the GALT, particularly in the distal ileum. Like Johne's disease of cattle, intestinal tuberculosis is a chronic wasting disease characterized by a roughened, rugaelike appearance to the intestine.

367

368

## Pathologic Basis of Veterinary Disease, 4th Edition

In small animals, it is sometimes clinically possible to palpate the thickened intestine. A thickened colon is sometimes palpable rectally in large animals. Granulomatous lymphadenopathy is often present, sometimes with mineralization and necrosis. The intestinal lamina propria and submucosa, as in Johne's disease, are enlarged and the architecture distorted by epithelioid macrophages and giant cells. Fewer acid-fast organisms are seen as compared with Johne's disease. In most cases of *Mycobacterium avium-intracellulare*-induced intestinal tuberculosis, lepromatous (noncaseating) granulomatous inflammation occurs similar to that of Johne's disease of small ruminants and dogs.

Pigs often contract intestinal tuberculosis as a result of the husbandry practice of feeding them avian litter as an inexpensive protein source. As might be expected, early lesions develop in the retropharyngeal lymph nodes.

### 7.2.9.18 DISEASES IN ANIMAL SPECIES

#### 7.2.9.18.1 Intestinal Diseases of Horses

##### 7.2.9.18.1.1 Bacterial

##### 7.2.9.18.1.1.1 *Rhodococcus equi* enteritis.

*Rhodococcus equi* is a soil saprophyte and a normal inhabitant of the equine intestine. The disease caused by this large, potentially zoonotic, gram-positive, facultatively anaerobic rod is often characterized by pulmonary pyogranulomas in foals under 6 months and in immunocompromised adult horses and human beings, or those with intercurrent disease (AIDS patients). The bacterium is not resistant to neutrophil-mediated destruction but can resist the intracellular environment of macrophages. All pathogenic *Rhodococcus equi* isolated from horses but not human beings have a large plasmid and the encoded surface-expressed lipoprotein VapA, which is associated with virulence. The frequent intercurrent of helminths and *Rhodococcus equi* infection suggests that migrating larvae aid in distributing the bacterium through the body of the foal. Stringent control of helminth infections may therefore help to reduce or eliminate *Rhodococcus equi* infection.

Equine abortion, pneumonia, and placentitis have been associated with infection, as have sporadic infections, sometimes fatal, of a wide variety of mammalian species. *Rhodococcus equi* can be isolated from a large number of otherwise healthy mammals of different species.

When coughed up and swallowed in large numbers, the bacteria enter the intestinal M cells overlying the GALT, resulting in pyogranulomatous lymphadenitis of GALT and lymph nodes and pyogranulomatous ulcerative enterotyphlocolitis.

Intestinal infection commences in Peyer's patches, which are ultimately replaced by granulomatous inflammation, abscess formation, and necrotic tissue, and the patches are ulcerated. Infection then spreads to mesenteric lymph nodes with a similar result. Macrophages, often laden with intact bacteria, fill the intestinal lamina propria and submucosa, resulting in a markedly thickened, corrugated intestine. The grossly observable abscesses and foci of necrosis and ulceration often correspond to the distribution of GALT (Fig. 7-145). Mesenteric, cecal, and colonic lymph nodes are enlarged, firm, and gray (Fig. 7-146). They may contain granulomas and abscesses. The large number of macrophages and multinucleated giant cells within the lamina propria and lymphoid

368

369

## Pathologic Basis of Veterinary Disease, 4th Edition

---

tissue is characteristic of this infection. Bacteria may be seen within these cells with Giemsa and tissue Gram stains. The florid inflammatory infiltrate expands the intestinal villi and may distort the crypts of the entire intestinal tract.

**Fig. 7-145 Multifocal ulcerative colitis, colon, horse.** *Rhodococcus equi* infection causes multiple mucosal ulcers centered over gut-associated lymphoid tissue. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-146 Mesenteric lymphadenitis, colon, horse.** Infection of colic lymph nodes with *Rhodococcus equi* causes pyogranulomatous lymphadenomegaly. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Contamination of cutaneous wounds by *Rhodococcus equi* may result in cutaneous ulcerative lymphangitis in horses. Swine cervical lymphadenopathy may also be a result of infection.

7.2.9.18.1.2

### Rickettsial

7.2.9.18.1.2.1

#### Equine monocytic ehrlichiosis.

Equine monocytic ehrlichiosis, also known as Potomac horse fever, was first reported in 1983. It appears that the disease was present for at least the previous 5 years. First described in the Potomac River valley of Maryland, Virginia, and Pennsylvania, it is now found throughout the United States and elsewhere. The common denominator is a proximity of horses to slow-moving bodies of water. Fever, depression, severe diarrhea, dehydration, and laminitis characterize the disease. Equine monocytic ehrlichiosis is apparently the same disease known as churrido equino (equine scours), which has been present for more than a century in Uruguay and Brazil.

The causative agent, *Ehrlichia risticii*—an intracytoplasmic rickettsial pathogen of epithelial cells, macrophages, and monocytes—is found in trematodes in freshwater snails. A reduction in pollution levels of the Potomac River basin is believed to have resulted in an increase in the number of freshwater snails. Mayflies and caddis flies have been implicated in transmission. Horses are believed to become infected by eating the dead flies that may accumulate in water buckets and feed troughs. Rickettsia are often transmitted by arthropods, and this disease is seasonal in northern latitudes (May through September). Without treatment, one third of cases with diarrhea die as a result of dehydration.

Clinical signs associated with equine monocytic ehrlichiosis include fever, watery diarrhea, depression, dehydration, variable colic, and subcutaneous edema of the thorax, abdomen, and hind legs. Experimental evidence indicates that *Escherichia risticii* may be abortigenic. The gross lesions of Potomac horse fever are subtle, consisting of congestion, petechiae, and edema, primarily in the cecum and colon. There is a variable superficial necrotizing enterocolitis. Sometimes the small intestine is affected. Intestinal contents are tan, watery, and malodorous.

Because the experimental reproduction of clinical disease in germ-free animals has not been done, the microscopic appearance of lesions is not certain. Intercurrent bacteria may be responsible for some of the reported lesions. Interestingly, horses with Potomac horse fever have a mild necrotizing typhlocolitis similar in distribution to colitis X and enteric salmonellosis. The nature of the gross lesions is somewhat controversial because experimental infections produce variable results. Like hog cholera, Potomac horse fever is sometimes associated with concurrent *Salmonella* infection, perhaps accounting for the *Salmonella*-like lesions.

Monocytes and macrophages in all layers of the intestine can be demonstrated with stains such as Giemsa to contain *Ehrlichia* organisms.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.18.1.3

Idiopathic

7.2.9.18.1.3.1

Equine granulomatous enteritis.

This sporadic disease, characterized by wasting and hypoalbuminemia, has been reported most often in thoroughbred and standardbred horses younger than 5 years old. The pathogenesis of the disease is unknown. In a few cases, *Mycobacterium avium* was isolated from lesions. The disease is characterized by diffuse or segmental transmural noncaseating granulomatous inflammation of the small and occasionally large intestines. Giant cells are present in about half the cases. The result is a notably thickened bowel (Figs. 7-147 and 7-148).

7.2.9.18.1.3.2

Clostridial enteritis (colitis X).

The severe diarrhea seen in cases of colitis X contains no blood and is rapidly fatal. The cause is unknown. However, the disease is associated with certain environmental and clinical variables.

369

These include exhaustion; shock or other stressors; enterotoxemia, perhaps associated with overgrowth of *Clostridium perfringens* type A (antibiotic enteritis); *Clostridium difficile*; or anaphylaxis. Lesions are limited to the mucosa of the cecum and colon and consist of edema, congestion, and hemorrhage (Fig. 7-149). The location and nature of these lesions overlap with those of acute enteric salmonellosis and equine monocytic ehrlichiosis. Therefore elimination of *Salmonella* spp. and *Ehrlichia risticii* as causes is necessary before a diagnosis of colitis X can be made. Thus colitis X is a diagnosis made by exclusion of other causes. At necropsy, in addition to the intestinal lesions, evidence of endotoxic shock, such as disseminated intravascular coagulopathy, thrombosis, and hemorrhage of the adrenal cortices (Waterhouse-Friderichsen syndrome) can be present, as in salmonellosis and other septicemic diseases.

Fig. 7-149 **Clostridial enteritis, colon, horse.** Commonly called “colitis X,” this disease is characterized by mucosal edema, congestion, and hemorrhage. The lesions are attributed to endotoxemia caused by *Clostridium perfringens* type A or *Clostridium difficile*. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.1.3.3

### Hemorrhagic fibrinonecrotic duodenitis-proximal jejunitis.

Also known as anterior enteritis and gastroduodenojejunitis, the morphologic description of the lesions is the same as the name of this idiopathic disease. The disease is characterized microscopically by submucosal edema and a neutrophilic infiltrate of the submucosa and lamina propria. *Salmonella* and clostridial infections are suspected as the cause. This disease occurs in horses older than 9 years of age, and the definitive diagnosis is made at necropsy by the characteristic hemorrhagic necrotizing lesions in the small intestine. The duodenum is always involved; jejunal involvement is variable.

7.2.9.18.1.3.4

### Chronic eosinophilic gastroenteritis and multisystemic eosinophilic epitheliotropic disease.

Soft stools accompanied by weight loss characterize this uncommon condition. The inflammatory reaction consists of eosinophils among other inflammatory cells in both nodular and diffuse accumulations within all portions and layers of the gastrointestinal system, salivary glands, and mesenteric lymph nodes. A circulating eosinophilia may be present. Clinical signs relating to the gastrointestinal system may include watery diarrhea and hypoproteinemia secondary to protein-losing enteropathy. The histology of the condition, especially the presence of eosinophils, suggests a hypersensitivity reaction that in at least one instance was associated with *Pythium* spp. infection. With the exception of the rare cases with a specific etiologic agent, affected horses die. The disease is associated with an up-regulated  $T_H2$  response and increased IL-5 production. In humans and occasionally in horses, the lymphoplasmacytic infiltrates in this condition are precursors to lymphosarcoma.

7.2.9.18.1.3.5

### Anaphylactoid purpura.

Leukocytoclastic vasculitis associated with numerous discrete foci of necrosis and hemorrhage throughout the intestine and in the mucosa of the larynx and skeletal muscles, is termed anaphylactoid purpura in the horse, and Henoch-Schönlein disease in human beings. Anecdotal evidence suggests that an Arthus-like hypersensitivity reaction to a streptococcal respiratory infection is the mechanism of lesion production.

7.2.9.18.2

## Intestinal Diseases of Ruminants

7.2.9.18.2.1

### Viral

7.2.9.18.2.1.1

### Bovine viral diarrhea.

Also known as mucosal disease, bovine viral diarrhea (BVD) affects cattle of all ages but is most common in animals 8 months to 2 years of age. In this respect, clinical cases are typically younger than in animals susceptible to Johne's disease. Animals infected early in life with noncytopathic BVD virus develop a persistent infection. Later in life, if exposed to cytopathic virus, they may have disease develop. Clinical signs may include anorexia, depression, profuse watery diarrhea with staining of the perineum and tail, agalactia, pyrexia, rumen atony, ptyalism, lacrimation, and a

370

371

## Pathologic Basis of Veterinary Disease, 4th Edition

---

mucopurulent nasal discharge. Multifocal, sharply demarcated erosions and ulcers in the tongue, gingiva, palate, esophagus, rumen, abomasum ([Fig. 7-150](#)), and coronary bands of the hooves characterize BVD. In the intestine, the characteristic lesion is sharply demarcated foci of necrosis in the epithelium over the GALT ([Figs. 7-151](#) and [7-152](#)). Calves infected in utero may have cerebellar hypoplasia, cataracts, microphthalmia, renal dysplasia, and other congenital defects develop. Abortions, stillbirths, and mummified fetuses can also result from in utero infection. Aborted calves often have enlarged hemal lymph nodes. BVD is caused by a pestivirus. Morbidity in a herd varies from 2% to 50%. All affected animals die.

**Fig. 7-150 Acute multifocal esophageal ulcers, esophagus, cow. A,** Grossly, there are multiple sharply demarcated ulcers (*vertically linear red streaks*) and similar areas covered by diphtheritic membranes (*vertically linear yellow-brown streaks*). The cause is the pestivirus of bovine viral diarrhea. **B,** Microscopically, there is a focus of necrosis of cells of the stratum basale and stratum spinosum caused by the pestivirus of bovine viral diarrhea. H&E stain. (**A,** *Courtesy Department of Veterinary Biosciences, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.* **B,** *Courtesy Dr. J.S. Haynes, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.*)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Lesions in the stratified squamous epithelium begin in the stratum spinosum. Necrosis of the epithelium is soon followed by the formation of erosions and ulcerations. Villous and crypt enterocytes become necrotic. There is lympholysis in the GALT. Follicular medullary regions of intestinal lymphoid tissue may be filled with cell debris and dead enterocytes. There is commonly a fibrinonecrotic pseudomembrane over the damaged GALT. Ulcerative lesions have already been described in the oral cavity, tongue, esophagus, and rumen.

A more common outcome from BVD infection occurs in immunocompetent animals that are seronegative at the time of exposure to either the cytopathic or noncytopathic virus. Variable signs develop, but they are mostly mild or subclinical. Most cattle in the United States have serologic evidence of exposure to nonvaccine BVD. Exotic ruminants may also become infected. Under certain circumstances pigs may become subclinically infected. This is of interest because the viruses of BVD and hog cholera are antigenically closely related. This may cause confusing serologic results when testing hogs for cholera. New world camelids may also succumb to BVD infection, although infections are often subclinical. The diagnosis of persistent infection is by immunohistochemistry of

371

skin biopsies because calves shed large amounts of virus through the skin. Feedlot cattle that are persistently infected are believed to be more susceptible to mannheimiosis, chronic pneumonia and polyarthritis syndrome, salmonellosis, infectious bovine rhinotracheitis, bovine respiratory syncytial virus, and mycoses. Other diagnostic means are virus isolation, reverse transcription (RT)-PCR, and antigen capture enzyme-linked immunosorbent assay (ELISA).

372

7.2.9.18.2.1.2

### Rinderpest.

Lesions similar to those of BVD occur in cattle with rinderpest. This morbillivirus disease of cattle, however, has characteristic multinucleate enterocytes in the intestinal lesions that do not occur in BVD. Rinderpest does not occur in the United States or Europe, but it is a significant disease in Africa and Asia. In immunologically naïve populations of animals, morbidity and mortality may be high. Recovered animals have solid immunity. Vaccines are efficacious.

7.2.9.18.2.1.3

### Malignant catarrhal fever.

Caused by closely related rhadinoviruses ( $\gamma$ -herpesviruses), malignant catarrhal fever occurs in a variety of species of ruminants, including cervids and bison. The African form of the disease, caused by alcelaphine herpesvirus-1 (AHV-1) is common in wildebeests and other ruminants. In the United States and worldwide, ovine herpesvirus-2 (OHV-2), caprine herpesvirus-2 (CpHV-2), and white-tailed deer herpesvirus (MCF-WTD) are most often reported in ruminants. The respiratory form of the disease, associated with keratoconjunctivitis, is most commonly seen in cattle in the United States.

Lesions include widespread lymphoplasmacytic necrotizing arteritis and phlebitis of the subcutis and especially in the rete mirabile surrounding the base of the pituitary gland. Hoof walls may be shed. Coagulation necrosis is found in lymph nodes, and lymphoplasmacytic infiltrates are present in the retina, myocardium, brain, spinal cord, and meninges. The alimentary form of the disease is characterized as multifocal ulcerative stomatitis, glossitis, esophagitis, abomasitis, and enterotyphlocolitis associated with vasculitis. Hemorrhagic cystitis may also be present.

7.2.9.18.2.1.4

### Winter dysentery.

Winter dysentery is a somewhat enigmatic, acute, generally nonfatal disease of adult cattle. As the disease progresses in a herd, virtually all members become ill. As the name implies, it is a seasonal

## Pathologic Basis of Veterinary Disease, 4th Edition

---

disease and additionally occurs only in northern latitudes. Catarrhal ileitis and jejunitis characterize this highly contagious disease.

Although its cause is unknown, a coronavirus has been implicated as causative and can sometimes be demonstrated immunohistochemically in colonic basal enterocytes of affected animals. Acute onset of profuse diarrhea, decreased milk production in dairy cattle, variable depression, and anorexia are characteristic. Malodorous green to black (melena) diarrhea lasts for up to 4 days and may contain fresh blood and mucus. Immunity in dairy herds is protective for years. Older animals are more severely affected than are younger ones. Calves appear to be refractory to disease development.

Mild lesions are noted in the rare animal that dies of winter dysentery. The intestinal mucosa is intact, but there is variable congestion and petechiae of the abomasum and small intestine. The intestine may be atonic. The colon may have congestion and hemorrhage of the colonic mucosal folds, a nonspecific lesion associated with tenesmus (tiger striping).

Diagnosis is generally made by epizootic information, clinical signs, its seasonal occurrence, and lack of significant mortality.

7.2.9.18.2.1.5

### Bovine torovirus diarrhea.

The shedding of bovine torovirus (Breda virus, BoTV) has been associated with diarrhea of neonatal veal calves. BoTV is a single-stranded, enveloped RNA virus, which currently cannot be grown in cell culture. BoTV is associated with the presence of other enteropathogens of neonates, including rotavirus, coronavirus, *Cryptosporidium*, *Salmonella*, and *Giardia*. Although it is not uncommon to have intercurrent infections producing diarrhea in calves, especially in the presence of immunosuppression, malnutrition, and other stressors, BoTV may cause disease independently. Necrosis and sloughing of enterocytes on the middle and lower villi, extending into the crypts, are noted on histologic examination. Diagnosis is confirmed by antigen-capture ELISA or RT-PCR in feces in the absence of evidence of other enteric pathogens. Death, when it occurs, is due to dehydration.

7.2.9.18.2.2

### Bacterial

7.2.9.18.2.2.1

### Paratuberculosis.

Paratuberculosis or Johne's disease has been described in numerous ruminant species. In cattle, the disease is characterized by intractable diarrhea, emaciation, and hypoproteinemia in animals older than 19 months. In the average infected herd, 32% to 42% of animals are infected. In small ruminants (sheep and goats), the clinical disease is similar to that observed in cattle except that diarrhea does not occur. The pygmy goat is an exception to the course of disease in small ruminants in that some pygmy goats have explosive diarrhea develop and die unexpectedly. In other ruminants, the disease has a protracted course and is considered a wasting disease because of the loss of body mass (Fig. 7-153). Ruminants are infected from feces-contaminated soil. Newer methods of bacterial classification suggest that the causative bacterium *Mycobacterium paratuberculosis* should be reclassified as *Mycobacterium avium* ssp. *paratuberculosis*.

372

373

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The causative organisms are very resistant to environmental stressors, particularly in regions with acid soils. After ingestion, the bacilli penetrate the gastrointestinal mucosa and are taken up by macrophages. Lesions in the lamina propria of the intestines, particularly in the ileum, include the accumulation of macrophages. There is little correlation between the severity of the gross lesions and the severity of clinical disease. An age-related immune resistance to infection and disease develops in animals older than 2 months. Fetuses can be infected, but disease is delayed until the animals are much older. Isolation of newborns from fecal contamination is a useful measure to reduce the incidence of infection in a particular herd.

Diagnosis is made by observing clinical signs together with the signalment. The gross lesion in Johne's disease is a chronic, segmental thickening of the ileum, cecum, and proximal colon (Fig. 7-154). The ileocecal valve region is usually affected. Affected segments have a variably thickened, rough, rugose mucosa, often with multiple foci of ulceration. There is mesenteric lymphadenopathy.

**Fig. 7-153 Granulomatous enteritis, Johne's disease**

**(*Mycobacterium avium* ssp. *paratuberculosis*), cow .**

There is chronic wasting and diarrhea in this 18-month-old heifer. The age at which this cow showed clinical signs is not typical of the disease. Signs usually occur two or more years after initial infection. (Courtesy College of Veterinary Medicine, Cornell University.)

Fig. 7-154 **Granulomatous enteritis, Johne's disease** (*Mycobacterium avium* ssp. *paratuberculosis*), ileum, sheep. There is notable thickening of the mucosa, which is smooth and shiny (intact) and not ulcerated. (Courtesy Dr. M.D. McCracken, College of Veterinary Medicine, University of Tennessee; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Noncaseating granulomas contain numerous foamy macrophages with large numbers of acid-fast organisms (Fig. 7-155). In contrast, sheep, goats, and deer may have tuberculoid (caseating) granulomas in the intestines, lymphatics, and lymph nodes. These granulomas are sometimes mineralized and contain whorled accumulations of epithelioid macrophages with variable numbers of Langhans'-type giant cells. It is more difficult to find acid-fast mycobacteria in these mature granulomas.

373

374

Fig. 7-155 **Granulomatous enteritis, Johne's disease** (*Mycobacterium avium* ssp. *paratuberculosis*), small intestine, cow. **A**, The lamina propria of the intestine is markedly expanded by granulomatous inflammatory cells, which compress the crypts and eventually result in their loss (atrophy). H&E stain. **B**, *Mycobacterium*-containing macrophages distend the lamina propria. Ziehl-Neelsen stain. (A and B, Courtesy Dr. P.N. Nation, Animal Pathology Services; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

*Mycobacterium avium* ssp. *paratuberculosis* can be isolated from feces of affected animals, from diseased intestines and regional lymph nodes, and sometimes from a variety of other tissues and fluids, including the liver, uterus, fetus, milk, urine, and semen. Acid-fast bacteria in rectal mucosal scrapings are found in 60% of the cases. Hepatic microgranulomas occur in about 25% of affected animals. Aortic mineralization (arteriosclerosis), when it occurs in association with the clinical signs and lesions of paratuberculosis, is specific for Johne's disease in cattle. The pathogenesis of this vascular lesion is not well understood but is associated with the severe cachexia associated with the disease. The epizootiology of Johne's disease leads many to believe it is one of the most important diseases facing the dairy industry. Speculation has existed for many years that Johne's disease is zoonotic and somehow causative of Crohn's disease in human beings.

7.2.9.18.2.2.2

### Hemorrhagic bowel syndrome of dairy cattle.

Also known as fatal jejunal hemorrhage syndrome and intraluminal-intramural hemorrhage of the small intestine, this condition of dairy cattle is characterized by intraluminal hemorrhage resulting in blood clots that lead to intestinal obstruction. It is characterized by dark, clotted blood in the feces;

## Pathologic Basis of Veterinary Disease, 4th Edition

---

variable and multifocal distention of the small intestine; small intestinal ileus; and necrohemorrhagic jejunitis or enteritis (Fig. 7-156). The cause is unknown, but *Clostridium perfringens* type A is suspected. The mortality rate is high.

7.2.9.18.2.3

### Miscellaneous

7.2.9.18.2.3.1

#### Chlamydiosis.

Bovine chlamydia (strains of *Chlamydia psittaci*) has been recovered from spontaneous enteritis of young calves. Affected calves have diarrhea, fever, anorexia, and depression. Following experimental inoculation, newborn calves have fever and diarrhea develop within 24 hours and become moribund within 4 to 5 days. Grossly the ileum is most severely affected, but the jejunum and large intestine also have lesions. In diseased segments, the mucosa is congested and marked with petechiae. The intestinal wall and mesentery are edematous. The lumen contains watery, yellow fluid mixed with a yellow, tenacious, fibrin-rich material attached to the surface. Colonic ridges are hyperemic and have small erosions. Bleeding from petechiae and ecchymoses of the colonic or rectal ridges occurs infrequently. Regional lymph nodes are enlarged.

Microscopically, villous epithelial cells, enterochromaffin cells, goblet cells, macrophages, fibroblasts of the lamina propria, and endothelial cells of lacteals are parasitized by the chlamydia. In the epithelial cells, the chlamydia are located in the apical cytoplasm. The chlamydia are endocytosed and multiply in epithelial cell apices. They subsequently are liberated into the lamina propria. Villi are enlarged by dilated lacteals and infiltrates of mononuclear cells and neutrophils. Crypts of both small and large intestines are dilated and have sloughed epithelial cells and inflammatory exudate (colitis cystica superficialis). The centers of lymphoid follicles of Peyer's patches are necrotic. The mucosa and submucosa of the intestines are thickened by a diffuse granulomatous reaction. The abomasum also has lesions, and, in some calves, foci of inflammation extend transmurally, thereby causing focal peritonitis.

374

375

Fig. 7-156 **Necrohemorrhagic enteritis, hemorrhagic bowel syndrome, small intestine, cow.** **A**, The massive small intestinal hemorrhage and necrosis is characteristic of clostridial infections of the intestine. **B**, Note the horizontal linear “band” of acute coagulative necrosis affecting the superficial half of the mucosa (*light pink zone*) of the intestine caused by clostridial toxins. H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. C.W. Qualls, College of Veterinary Medicine, Oklahoma State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 7.2.9.18.3 Intestinal Diseases of Pigs

Enteric diseases of pigs are an important cause of economic loss. Rapid and accurate on-farm diagnosis is critical in controlling disease outbreaks. If one takes into account the epidemiology of the outbreak and the age of the affected animals and the location and nature of lesions, one can generally be fairly accurate in rendering an on-farm diagnosis, pending laboratory confirmation. This listing of specific infectious causes of enteritis in pigs is exclusive of those agents already discussed. When formulating a differential diagnosis, all causes of enteritis must be considered, including intestinal displacements, colibacillosis, rotavirus, *Salmonella*, parasites, toxins, and so on.

#### 7.2.9.18.3.1 Viral

##### 7.2.9.18.3.1.1 Transmissible gastroenteritis.

Transmissible gastroenteritis (TGE) is an important disease in pigs younger than 10 days. The coronavirus that causes this disease cross-reacts with, but is distinct from, the coronavirus that causes feline infectious peritonitis. The virus is inactivated by sunlight; therefore TGE disease occurs mostly in winter. Piglets suffer from acute diarrhea, weight loss, vomiting, and dehydration. Morbidity and mortality, especially in neonates, approach 100% in susceptible herds. Death occurs within 48 hours to 5 days after the commencement of clinical signs. Target cells for the virus are villous enterocytes, and therefore lesions consist of notable atrophy of villi of the small intestine (Fig. 7-157). Sows are susceptible to the virus, and morbidity among the sows is 100%, but the clinical signs are mild and transient (fever, vomiting, inappetence, agalactia), and none die. Immunity is complete. Diagnosis is by positive immunostaining of intestinal sections in piglets acutely ill with the disease.

Similar to rotavirus or non-TGE coronavirus infections, the virus is lytic and sloughed enterocytes carry virus into the feces. The difference in pathogenicity between rotavirus and non-TGE coronavirus infections and TGE is the number of villous enterocytes destroyed by a virus. In TGE, most of the villous enterocytes are destroyed and therefore the clinical disease is more severe.

The diarrhea contains odoriferous undigested milk. The loss of the majority of villous enterocytes results in continued significant intestinal malabsorption. Because of fusion of adjacent villi, the enterocyte mass may never fully be restored. Affected surviving animals remain chronic “poor doers.” In feeder pigs, transmissible gastroenteritis virus infection causes transient clinical signs with eventual recovery.

Piglets dead from TGE are dehydrated and their perineum is stained with liquid, yellow, fecal material. The small intestine is dilated and thin walled because of the loss of enterocytes, and contains yellow fluid and gas (Fig. 7-158). Mesenteric lymph vessels are devoid of chyle as a result of malabsorption. The diagnosis is partially based on the presence of villous atrophy. The decrease in villous height: crypt depth ratio is marked and may be appreciated subgrossly (Fig. 7-159). Colibacillosis, coccidiosis, cryptosporidiosis, rotavirus infection, and non-TGE coronavirus infection are among the differential diagnoses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.3.2

Bacterial

7.2.9.18.3.2.1

Swine dysentery.

---

Unlike most of the other diseases of the porcine gut, swine dysentery is generally confined to the large intestine. The gross lesions of the disease closely approximate those of acute enteric salmonellosis except that bloody feces are more usual in dysentery. Weanling pigs 8 to 14 weeks old are usually affected, and the disease spreads rapidly through a herd. Morbidity approaches 90%, and mortality is around 30%. Lesions of mucohemorrhagic enteritis are present in the spiral colon, colon, cecum, and rectum. The intestine often has a fibrinonecrotic pseudomembrane that correlates with the severe diarrhetic feces that contains blood, mucus, and fibrin ([Fig. 7-160](#)). The diarrhea and electrolyte loss that occur are caused by colonic absorptive failure.

375

376

**Fig. 7-157 Transmissible gastroenteritis, small intestine, piglet. A,** Early stage of the disease. Transmissible gastroenteritis virus targets epithelial cells of the tips and upper sides of intestinal villi causing necrosis of the enterocytes and atrophy of the villi. These cells are sloughed and replaced by flattened epithelial cells migrating up the basement membrane from progenitor cells in the crypts. *Inset:* Note the flattened epithelial cells covering the tips and sides of the atrophic villi and the fusion of the adjacent villi. Inflammation is minimal. H&E stain. **B,** Later stage of the disease. There is severe blunting (marked villus atrophy) of intestinal villi with fusion of their basement membranes. Chronic inflammation is prominent in the lamina propria and submucosa. H&E stain. (**A,** Courtesy Dr. B.G. Harmon, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B,** Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-158 **Transmissible gastroenteritis, small intestine, piglet.** The small intestine is dilated by gas, is thin walled, and contains undigested milk. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 7-159 **Wet mount, intestinal villi, transmissible gastroenteritis, small intestine, piglet.** There is notable villous atrophy (bottom) compared with normal intestine (top). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

The causative bacterium, *Brachyspira hyodysenteriae*, previously known as *Treponema* and *Serpulina*, acts synergistically with anaerobic colonic flora, such as *Fusobacterium necrophorum* or *Bacteroides vulgatus* to produce disease. This synergism is believed to be partially responsible for the age restriction (8 to 14 weeks old) of the disease because neonatal animals have not yet developed the appropriate anaerobic gut flora. *Brachyspira hyodysenteriae* produces a cytotoxic hemolysin, which is a virulence determinant. *Brachyspira hyodysenteriae* is identified by impression smear (Fig. 7-161), dark-field microscopy, immunolabeling techniques, and by newer methods, such as PCR.

### 7.2.9.18.3.2.2

#### *Lawsonia enteritis.*

This disease manifests in a variety of ways as indicated by the number of names applied to it: proliferative enteropathy, proliferative ileitis, intestinal adenomatosis, distal ileal hypertrophy, terminal ileitis, and proliferative hemorrhagic enteropathy. The genus of the causative agent has undergone several recent changes in nomenclature. For many years, this disease was believed to be caused by *Campylobacter* spp. (*Campylobacter sputorum mucosalis*, *Campylobacter jejuni*, *Campylobacter hyointestinalis*). Newer methods of bacterial classification caused the name to be changed first to *Ileobacter* and now *Lawsonia*. Pigs older than 4 weeks of age are susceptible; thus this condition is a postweaning disease. The nature of the lesions is a function of the extent of intestinal mucosal necrosis. The disease begins as a bacteria-induced stimulation of intestinal crypt epithelial cells of the small intestine, particularly in the ileum (Figs. 7-162 and 7-163). Lesions are generally most severe in the ileum. With time, the lesions progress to necrosis of the proliferating crypt cells with hemorrhage (Fig. 7-164). Thus the morphologic appearance of the lesions varies from case to case. The mechanism of lesion production is not well understood. Infection results in immunosuppression with a reduction in CD8<sup>+</sup> T lymphocytes and B lymphocytes. In the proliferative form of the disease, the causative bacteria may be seen in apical cytoplasm of enterocytes. The enterocyte hyperplasia that results may cause release of cytokines that attract macrophages. With severe disease, bacteria are present in macrophages in the lamina propria. This may cause release of tumor necrosis factor- $\alpha$  resulting in vascular permeability and hemorrhage.

376

377

Fig. 7-160 **Necrohemorrhagic enterocolitis, swine dysentery, spiral colon, pig.** There is marked necrosis and hemorrhage of the intestinal mucosa caused by the bacterium *Brachyspira hyodysenteriae*. ## Pathologic Basis of Veterinary Disease, 4th Edition

Morbidity within a herd is 10% to 15%; mortality is around 50%. In fatal cases, affected pigs usually die within a day of the appearance of clinical signs. Pigs that recover are generally “poor-doers.” At clinical and necropsy examination, variable amounts of blood and intestinal casts are present in the feces. Microscopically the comma-shaped bacteria are made visible with special stains, such as Steiner's, within the mitotically active cells of the small intestinal villous crypts (Fig. 7-165). The massive mitoses of crypt cells and resultant cryptal crowding and necrosis prevent maturation to absorbent villous enterocytes. There is resultant villous shortening. Mitosis can be so intense that the histologic features suggest neoplasia and a diagnosis of “intestinal adenomatosis.” A similar organism and associated intestinal proliferation are found in horses, hamsters, ostriches, cervids, and macaques.

7.2.9.18.3.2.3

### Glasser's disease.

Glasser's disease is characterized by fibrinous polyserositis (pleuritis, pericarditis, peritonitis, arthritis, and leptomeningitis). Although not generally a diarrheal disease, it causes inflammation of the intestinal serosa (serositis). Lesions range from arthritis to peritonitis to leptomeningitis depending on the serous surface infected. Glasser's disease generally occurs in 5- to 12-week-old pigs. Mortality of affected animals within a herd is high, but morbidity is low. Although classic Glasser's disease is caused either by *Haemophilus suis* or *Haemophilus parasuis*, porcine polyserositis can be caused by *Mycoplasma hyorhinis*, *Streptococcus suis* type II (zoonotic), septicemic salmonellosis, and septicemic *Escherichia coli* (Fig. 7-166).

377

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.3.2.4

### Miscellaneous

7.2.9.18.3.2.4.1

#### Chlamydia infection.

*Chlamydia* has been found in enterocytes of normal pigs and pigs with diarrhea. In gnotobiotic pigs, *Chlamydia trachomatis* and *Chlamydia suis* infection results in villous atrophy and villous-tip necrosis. These lesions are most severe in the distal jejunum and ileum. Colonic infection has also been reported.

7.2.9.18.3.2.4.2

#### Intestinal emphysema.

Intestinal emphysema (pneumatosis cystoides intestinalis) of pigs and rabbits translates to gas-dilated lymphatics of the intestinal serosa and mesentery. The cause of this condition is unknown, and it is not associated with clinical disease (Fig. 7-167).

**Fig. 7-165 Proliferative enteritis, ileum, pig.** Curved *Lawsonia* spp. bacteria (arrow) are present in the apical cytoplasm of enterocytes. There is proliferation of crypt enterocytes. Warthin-Starry stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-166 **Fibrinous polyserositis, abdomen, pig.** Strands and clumps of fibrin are scattered throughout serosal surfaces. A milk-spotted liver is also present. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.18.4 Intestinal Diseases of Carnivores

7.2.9.18.4.1 Viral

7.2.9.18.4.1.1 Parvovirus enteritis.

Parvovirus enteritis of dogs and cats is a severe, usually fatal disease. Because the target cells are those that are rapidly dividing in the intestine, the crypt cells are principally affected. This tropism is called radiomimetic. Identical crypt lesions are sometimes associated with FeLV infection. Initial virus replication occurs in lymphoid tissue. Although there is much overlap in the disease syndrome in dogs and cats, the dissimilarities warrant independent discussion of each species.

378

379

**Fig. 7-167 Intestinal emphysema, intestines, pig.** Gas bubbles dilate serosal and mesenteric lymphatics. (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

In the cat, mink, and raccoon, panleukopenia, cat distemper, feline enteritis, and mink enteritis are synonyms for this important disease. The clinical disease is characterized by dehydration, depression, and vomiting. Because the bone marrow is a rapidly dividing tissue, panleukopenia dominates the clinical pathologic findings.

Early lesions in the course of the disease are lymphoid depletion and thymic involution. Later, lesions include flaccid, segmentally reddened intestine with serositis. Lesions are generally limited to the small intestine, but colitis occurs in some cats. Villous atrophy occurs secondary to crypt cell destruction ([Fig. 7-168](#)). Basophilic intranuclear inclusion bodies are present in enterocytes and lymphocytes early in infection. In germ-free cats with a low enterocyte turnover, the disease caused by feline parvovirus is much less severe. Intrauterine infection causes congenital cerebellar hypoplasia of kittens. The virus, as described previously, is cytolytic and infects dividing cells and thus alters the differentiation of layers in the cerebellum during organogenesis.

Canine parvovirus enteritis first appeared in Europe and the United States in 1978. The disease was initially recognized because of the gross and microscopic lesions that were identical to those of feline parvovirus enteritis. Panleukopenia vaccines were effective in preventing this disease in dogs and were used extensively until canine-specific parvovirus vaccines were developed. Rottweilers and Doberman pinschers, which are genetically related, are at increased risk for parvovirus disease even if properly vaccinated.

Canine parvovirus disease initially was described as occurring in three distinct syndromes. Puppies younger than 2 weeks of age had generalized disease with focal areas of virus-induced necrosis in

## Pathologic Basis of Veterinary Disease, 4th Edition

those tissues with rapidly dividing cells. Thus multiple organs and tissues, such as the liver, kidney, heart, vessel, bone marrow, intestine, and lung are affected. Puppies 3 to 8 weeks of age would sometimes have myocarditis develop for the same reason. Often initial infection would go undetected, and these animals would die unexpectedly up to 5 months later because of myocardial scarring and conduction failure. In puppies 8 weeks or older, the disease is identical to that in the cat. Cerebellar hypoplasia has not been induced in puppies.

At necropsy, the dilated, fluid-filled, flaccid, hemorrhagic, small intestine with serositis similar to that of panleukopenia is quite characteristic (Fig. 7-169, *A*). The contents of the small intestine are brown to red-brown and fluid with a fibrinous exudate, with or without hemorrhage (Fig. 7-169, *B*). Mesenteric lymphadenomegaly with variable hemorrhage is present. The bone marrow is depleted. Dogs, but not cats, may have coagulative lymphadenitis associated with severe lymphoid infection.

The intestinal lesion is necrosis of crypt epithelial cells. Surviving epithelial cells are not targets of the virus, but their morphology changes to squamoid to cover the surface of the denuded crypts and later to temporarily cover the denuded villous basement membrane, as replacement cells are not being produced, even though senile epithelial extrusion continues to occur from the villous tips.

379

Severe lesions consist of partially denuded villi over debris-filled crypts, some of which lack an epithelial lining. Because the villous basement membrane is exposed during the continuing extrusion process, villous fusion occurs, resulting in lack of a scaffold for enterocyte replacement once the crypts recover and in permanent villous distortion and atrophy. Hyperplastic crypt epithelium may therefore be present. Inclusion bodies are not present in lymphoid tissue. In bone marrow, erythropoiesis is normal, but granulopoiesis is reduced. Necrotizing colitis may occur but is much less important than the small intestinal lesions.

380

**Fig. 7-168 Panleukopenia virus enteritis, small intestine, cat.** Villi are denuded of epithelium and are atrophic. Some crypts are dilated. Note the squamoid epithelial cells in some crypts and hyperplasia in others, all indicative of attempts at epithelial repair and regeneration. Chronic inflammatory cells are present in the lamina propria. H&E stain. *Inset:* Higher magnification of crypts showing viral-induced degeneration, necrosis, and sloughing of epithelial cells. H&E stain. (**Figure and Inset**, courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-169 **Parvovirus enteritis, small intestine, dog.** **A**, Segments of the small intestine are diffusely reddened (active hyperemia of the mucosa), and the serosal surface is roughened, faintly granular, and petechiated. **B**, The mucosa of the small intestine is necrotic. Note the roughened, granular, focally petechiated, and focally sloughing mucosa. (**A**, Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Department of Veterinary Biosciences, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Dogs with hemorrhagic parvovirus enteritis have bloody diarrhea and die from shock within 24 hours. Secondary bacterial infections with endotoxemia are believed to be associated with this syndrome.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.4.1.2

### Minute virus of canids.

Canine parvovirus type 1 produces myocarditis and respiratory disease in young pups. The virus is widely distributed in the canine population, but disease is only diagnosed sporadically. The virus is spread via the oronasal route. Fetal death and embryo absorption occur between 25 and 35 days of gestation. Microscopically, intestinal lesions consist of enterocyte hyperplasia with eosinophilic or amphophilic intranuclear inclusion bodies in the enterocytes of the villous tips of the duodenum and jejunum. Crypt necrosis characteristic of canine parvovirus type 2 infection is not present.

7.2.9.18.4.1.3

### Feline infectious peritonitis.

Feline infectious peritonitis (FIP) is a uniformly fatal disease of cats. Although it affects cats of all ages, the disease is principally found in the young and old. Twelve percent of feline deaths are associated with FIP. The cause of the disease is a coronavirus related to the coronavirus of transmissible gastroenteritis of pigs. After entry into the body, the first round of viral replication takes place in the lymphoid system. Macrophages are infected and carry the virus systemically. Endothelial cells are activated secondary to up-regulation of major histocompatibility complex II. Recent observations suggest that activated monocytes are critical for development of vasculitis. Lesions are multifocal and most organs, including the central nervous system, may be affected. The lesions in the vasculature of the eye are sometimes useful in making a tentative diagnosis of FIP in the live cat, but other diseases, such as toxoplasmosis and systemic fungi, may cause similar lesions. The “wet form” of the disease is characterized by fibrinous polyserositis ([Fig. 7-170](#)); the “dry form” is without the effusive process. Why one form develops rather than the other is not completely understood, but may relate to the major type of immune effector cell. The disease often clusters in households, and virus spreads among cats by saliva on shared bowls and utensils or by mutation of an endogenous coronavirus.

380

381

**Fig. 7-170 Fibrinous polyserositis, abdomen, cat.** Fibrin strands between viscera and mats of fibrin on organ surfaces are characteristic of the “wet form” of feline infectious peritonitis. The mesentery (below and left of the liver) has numerous white linear serpentine tracts, which are inflamed (type III hypersensitivity, immune complex) capillaries and venules. Note the small nodules (pyogranulomas) on the intestinal serosa and on the surface of the kidney. (*Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.*)

Because of the presence of a nonneutralizing antibody, immune complexes develop and Arthus reactions localize in the vasculature. Complement is fixed, and inflammatory cell chemoattractants are produced. Vasculitis results in protein effusion. Thus lesions are vasocentric. The prodromal course of FIP is shortened, and the development and extent of lesions are accelerated in seropositive cats. FIP is usually characterized by progressive wasting because of protein loss. It is unusual for a virus to result in pyogranulomatous lesions, but in FIP the vasocentric deposition of immune complexes results in pyogranulomas. These lesions are single to multiple, white, and raised. On the surface of the kidney, they often are linear, clearly following the renal surface vasculature. In its “wet form,” FIP is characterized by variable amounts of thick, stringy, high-protein effusion in body cavities. When placed between gloved fingers, this transudate may be drawn out in strings as the fingers are separated. The transudate is sterile, eliminating most other causes of fibrinous peritonitis. The granulomas are translucent and less than 2 mm in diameter. The “dry form” of the disease is identical to the wet, but contains only pyogranulomas and not the exudates.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.18.4.2

### Bacterial

7.2.9.18.4.2.1

#### Histiocytic ulcerative colitis.

Because of its occurrence in boxer dogs and the genetically related French bulldog, this disease has been called boxer colitis. Granulomatous colitis is another term for this disease, although true granulomas are not present. It generally occurs in dogs younger than 2 years. Dogs can have soft feces, but often no diarrhea or weight loss is observed. In some cases, mucus and blood appear in the stool. The lesions, which are visible by proctoscopy, are raised ulcerative nodules (Fig. 7-171). Microscopically the colon is ulcerated and has marked infiltration by macrophages containing PAS-positive material.

Large macrophages with abundant foamy eosinophilic cytoplasm are present in the colonic lamina propria and submucosa early in the disease process. There may be lesser numbers of smaller, mononuclear inflammatory cells, principally lymphocytes and plasmacytes. The PAS-positive material in macrophages has been visualized by tissue Gram stains, electron microscopy, and immunohistochemistry. They likely contain bacteria and the phagolysosomal remnants of digested cells. Evidence suggests that the bacteria are probably *Escherichia coli*. The massive numbers of engorged macrophages within the lamina propria results in a space-occupying lesion that affects the overlying enterocytes. Enterocyte necrosis results in colonic erosion and ulceration. There is lymphadenopathy, both regional and generalized, characterized by an influx of foamy macrophages in the lymphatic sinuses.

**Fig. 7-171 Histiocytic ulcerative colitis, colon, boxer dog.** There are numerous round and coalescing ulcers in the colon in this case of “boxer colitis.” Recent research suggests *Escherichia coli* as the causative agent of boxer colitis. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.4.2.2

### Citrobacter freundii enteritis.

Bacteremia and septicemia associated with *Citrobacter freundii* have been reported to cause mucohemorrhagic diarrhea in dogs with hemorrhagic lesions in the small intestine and colon. It is believed to be a condition of puppies and immunocompromised dogs. Being bacteremic and/or septicemic, many organs and tissues are affected besides the gut. The condition is more common in humans as a nosocomial infection with a high mortality rate. In humans, the route of infection is through the urinary tract, gallbladder, gastrointestinal tract, or cutaneous wounds. *Citrobacter* infections should be considered potentially zoonotic.

7.2.9.18.4.3

### Fungal

7.2.9.18.4.3.1

### Canine histoplasmosis.

Canine histoplasmosis occurs most often in the Ohio and Mississippi River valleys. This zoonotic systemic fungus can infect the intestine, but pneumonia is more common. Thus the route of infection is inhalation or ingestion. The reservoir is believed to be soil and bird feces. The yeast invades tissue, causes necrosis, and replicates in macrophages. Granulomatous lesions may be present in pulmonary, intestinal, lymphoid, hepatic, and other tissue. Signs of intestinal histoplasmosis in the dog include intractable chronic diarrhea with anorexia and its attendant weight loss, lethargy, poor pelage, and anemia. Respiratory signs and peripheral lymphadenitis may be present. At necropsy or biopsy, the intestine has a thickened and corrugated mucosa with ulceration. There is hepatomegaly and mesenteric lymphadenopathy and lymphadenomegaly. Scattered pulmonary granulomas may be present.

381

382

In the affected ileum and colon, the lamina propria is widened by macrophages that contain *Histoplasma capsulatum* (Fig. 7-172). With time, infection may extend transmurally through the intestine and to the lymphoid system. There is hyperplasia of regional lymph nodes, and lymphoid sinuses contain numerous macrophages. Multifocal granulomas with intracellular fungi are in the liver, presumably arriving via the portal vein.

7.2.9.18.4.4

### Rickettsial

7.2.9.18.4.4.1

### Salmon poisoning.

This acute and fatal hemorrhagic granulomatous enterocolitis of the dog and fox results from consuming salmon carrying the fluke *Nanophyetus salmincola*. When this trematode harbors *Neorickettsia helminthoeca*, a 0.3- $\mu$ m coccoid rickettsia, disease may result. Six to eight days after eating parasitized fish, affected canids become febrile and depressed. There is an oculonasal discharge, severe diarrhea, emesis, anorexia, and splenolymphadenopathy characterized by enlarged tonsils, spleen, and lymph nodes. The mesenteric lymph nodes are often more severely affected than peripheral nodes. Unless treated, affected animals die within 10 days. Lesions may extend from the pylorus to the anus. The enteric lesions consist of hemorrhage at sites of GALT necrosis, especially near the ileocecal valves. In the small intestine, trematodes may be embedded in the mucosa. Diagnosis is confirmed by visualizing macrophages in many tissues, including the brain, containing Giemsa-stained elementary bodies.

Fig. 7-172 **Histoplasmosis, intestine, dog.** **A**, The mucosa is greatly thickened and congested due to granulomatous inflammation that expands the lamina propria. **B**, Clusters of 3- to 5- $\mu$ m *Histoplasma capsulatum* organisms with a central nucleoid are located in macrophages within the granulomatous inflammatory cells shown in Fig. 7-172, A. Grocott-Gomori's methenamine silver stain. (**A**, Courtesy Dr. R. Panciera, School of Veterinary Medicine, Oklahoma State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

7.2.9.18.4.5

### Parasitic

7.2.9.18.4.5.1

#### Canine multifocal eosinophilic gastroenteritis.

Canine multifocal eosinophilic gastroenteritis is an uncommon disease of dogs generally younger than 4 years. It is caused by migrating larvae of *Toxocara canis*. Therefore this disease occurs in association with poor parasite management. Chronic diarrhea, moderate weight loss, intermittent or persistent eosinophilia, and elevated serum  $\beta$ -globulin concentrations characterize this disorder. Serum albumin concentration, absorption tests, and small bowel contrast radiographs usually are normal.

Larvae of *Toxocara canis* are ingested, invade the mucosa of the stomach and small intestine, and then become trapped and localized in their self-induced inflammation. Dormant larvae migrate into the uterus and fetuses during late pregnancy. Postpartum, larvae are secreted in the milk of the bitch or ingested from environmental feces. Ingested larvae penetrate the gastric and small intestinal mucosa, enter lymph vessels or the portal vein, and travel to the liver and lungs. They then develop into third-stage larvae and are coughed up and swallowed. In the gastrointestinal tract, they mature to adult ascarids. In the majority of puppies, ascarid larvae complete their life cycle in several weeks. Alternatively the larvae are enveloped in granulomas that kill the parasite secondary to immune reactivity. These granulomas may occur anywhere along the parasite's migration tracts, including most abdominal organs, eyes, brain, and the lungs. Eosinophils are a prominent component of the inflammatory reaction and are attracted to the site of parasite entrapment by the waste products of the larvae. There may be subsequent mineralization of larvae, or they may remain viable for up to 4 years. This condition is especially common in aberrant host species and is called visceral larval migrans. It is an environmental danger where children play in sand or dirt contaminated by feces of infected animals. The ova are relatively resistant to environmental extremes.

382

383

Lesions are microscopic to macroscopic, may be quite numerous, and may be grossly visible. As in other inflammatory diseases, there may be regional lymphadenopathy with or without nodules that vary from principally granulomatous to eosinophilic or a mix of the two. Larvae, when present, are surrounded by an eosinophilic, amorphous, fringed material that stains PAS-positive (the Splendore-Hoeppli phenomenon). In general, canine multifocal eosinophilic gastroenteritis is asymptomatic.

7.2.9.18.4.6

### Immunologic

7.2.9.18.4.6.1

#### Inflammatory bowel disease.

In dogs and cats, this disease is microscopically a lymphoplasmacytic enteritis. Diagnosis is made by biopsy. Breeds with a predilection for this disease include the basenji and the German shepherd. The cause is unknown, but the presence of numerous lymphocytes and plasma cells suggests an immunologic problem. Malabsorption and chronic protein-losing enteropathy can result from the marked infiltrate of lymphocytes and plasmacytes in the lamina propria. In dogs, there are increased numbers of both B and T lymphocytes in the lamina propria of the small intestine (Fig. 7-173). In cats, but not dogs, dietary antigens cause some cases of inflammatory bowel disease; therefore

## Pathologic Basis of Veterinary Disease, 4th Edition

---

control of the disease can be achieved by regulation of the diet. Anecdotal evidence suggests that lymphocytic plasmacytic enteritis in the cat can be a prelude to intestinal lymphosarcoma.

**Fig. 7-173 Lymphoplasmacytic enteropathy, intestine, dog.** The lamina propria is widened with lymphocytes and plasma cells. H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.18.4.6.2

### Diffuse eosinophilic gastroenteritis.

Although this type of eosinophilic gastroenteritis has a predilection for the German shepherd breed, it occurs in other breeds of dogs and in cats. It is characterized by recurrent episodes of diarrhea associated with tissue and circulating eosinophilia. The increased concentration of eosinophils in the circulation and within lesions suggests a hypersensitivity reaction to some ingested substance or to parasites. The cause has not been identified. There are no gross lesions. Eosinophils, along with lymphocytes and plasma cells, heavily infiltrate all layers of the mucosa of the stomach and intestine.

7.2.9.18.4.6.3

### Wheat-sensitive enteropathy of Irish setters.

This hereditary condition, similar to gluten-sensitive enteropathy of human beings, is the first described dietary-induced enteropathy of dogs. It is characterized initially by increased numbers of intraepithelial lymphocytes and goblet cells and later by partial villous atrophy, particularly of the jejunum. Dietary therapy is palliative.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.18.4.7 Idiopathic

7.2.9.18.4.7.1 Feline ulcerative colitis.

Feline ulcerative colitis is grossly and histologically analogous to its canine counterpart, histiocytic ulcerative colitis (Fig. 7-174). The causative agent is unknown.

7.2.9.18.4.7.2 Canine senile gastrointestinal amyloidosis.

Amyloid located in and around vessels of the submucosal and muscular layers of the alimentary tract and within the mesentery has been reported in dogs. The mechanism and chemical nature of the amyloid deposition has not been determined. Dysfunction of the alimentary tract has not been reported to occur with this condition.

7.2.9.19 PARASITIC ENTERITIDES

Parasites of the intestinal tract are legion in the various domestic animal species. Refer to a parasitology textbook for specific information regarding the life cycles and identification of the various species. Diagnosis of enteric parasitism is generally performed via fecal flotation or intestinal scrapings.

383

384

**Fig. 7-174 Feline ulcerative colitis, colon, cat.** There are numerous round ulcers in the mucosa. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

7.2.9.19.1 Amebiasis

*Entamoeba* spp. are obligate intracellular parasites with a direct life cycle. The portal of entry is oral. Trophozoites are produced that dwell in the intestinal lumen. They may also invade through the intestinal wall and go to many other organs, such as the liver, brain, and lung, especially in humans, in whom microabscesses may form. Cysts are excreted with formed feces and continue their life cycle when ingested by another host. Trophozoites are more likely seen in diarrheic feces. Because cysts are the

## Pathologic Basis of Veterinary Disease, 4th Edition

---

infective form, diarrheic feces of dogs are not usually considered to be especially dangerous to humans or other animals. The trophozoites vary from 12 to 30  $\mu\text{m}$  in diameter, and the cysts vary from 10 to 20  $\mu\text{m}$  with four nuclei. Contact of ameba and host cells is likely mediated by adhesins. Soluble factors produced by the parasite mediate pathogenicity.

*Entamoeba histolytica* is zoonotic in human beings, other primates, dogs, cats, and other animals. Disease is serious in humans. Lesions include colonic congestion, petechia, and ulceration (ulcerative colitis). This colitis may be acute or chronic, bloody or mucoid. In tissue, the amebas may be as large as 50  $\mu\text{m}$  and often form typical flask-shaped ulcers spanning the mucosa and submucosa of the colon.

7.2.9.19.2

### Trichomoniasis

*Tritrichomonas foetus* is a sexually transmitted pathogen of cattle. Cats, especially those less than a year of age housed in groups, have a tendency toward large bowel diarrhea when infected with this flagellate. Diagnosis is often made by visualization of motile flagellates on fecal wet mounts. Histologic diagnosis is most accurate when at least six biopsy sections of colon containing surface mucus are examined. PCR on paraffin-embedded tissue has also been successful, even in the absence of histologic evidence of the parasite. Infection occurs in the ileum, cecum, and colon. Lesions include mild to moderate colitis, with microabscesses and occasional extension of infection into the lamina propria. There may be colonic enterocyte attenuation and/or increased mitotic activity in the crypts. The 5  $\mu\text{m}$  by 7  $\mu\text{m}$  teardrop-shaped parasites can often be seen in surface mucus, within colonic glands, and occasionally within macrophages and lymphatics. Thus the parasite is at least enteroinvasive under certain circumstances. Flagella are not visible on H&E staining. There is no effective treatment. The diarrheal disease in cats generally resolves within 2 years of onset.

7.2.9.19.3

### Coccidiosis

Coccidia are exquisitely host- and tissue-specific protozoa. They are obligate intracellular pathogens. Lesions vary from proliferative in sheep and goats (Fig. 7-175), to hemorrhagic in dogs, cats, and cattle (Fig. 7-176). In pigs, a fibrinonecrotic pseudomembrane, without blood, in 5- to 7-day-old animals is characteristic of enteric coccidiosis (Fig. 7-177). Most species of *Eimeria* and *Isospora* infect villous or crypt epithelial cells, more rarely lacteals, the lamina propria, and regional lymph nodes. The coccidia undergo one or more asexual reproductive cycles within enterocytes. The resulting sporozoites produce schizonts containing merozoites, which infect additional enterocytes.

Merozoites, produce gamonts that differentiate into microgametes and macrogametes. Microgametes fertilize macrogametes, producing zygotes that develop into oocysts. When a small number of coccidia parasitize in the intestine of otherwise healthy young growing animals, little disease results. However, when animals are in crowded conditions associated with poor sanitation, fecal-oral transmission of large numbers of organisms can occur. It is in these circumstances, compounded by malnutrition and intercurrent infections or parasitism, that clinical disease results. Enterocyte rupture occurs in all stages of the parasite's life cycle. Clinical disease is dependent on parasitic load and varies by animal species. Because of diminished epithelial turnover in young animals, they are most susceptible to disease.

"Poor doing" associated with diarrhea is characteristic of clinical coccidiosis. Depending on the host species and the region of intestine that is affected, infected fresh blood may be present in the feces. The presence of tenesmus is variable. Oocysts are demonstrable in the feces.

## Pathologic Basis of Veterinary Disease, 4th Edition

Gross lesions of coccidiosis are variable by host species, parasite species, and intestinal location. Bleeding is variably present both within species and among species. Coccidiosis in sheep and goats is characterized by enterocyte proliferation that is visible grossly as mucosal nodules (Fig. 7-178). The large schizonts of some species are sometimes grossly visible as well.

384

385

**Fig. 7-175 Multifocal proliferative enteritis, small intestine, goat.**

Proliferative nodules in the small intestinal mucosa are characteristic of ovine and caprine coccidiosis. Sporozoites and merozoites infect enterocytes and replicate, resulting in physical expansion of the cell (hypertrophy). (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

**Fig. 7-176 Necrohemorrhagic enteritis, small intestine, calf.** Coccidiosis in dogs, cats, and cattle is characterized by intestinal hemorrhage, or hemorrhagic diarrhetic feces may be visible on the perineum and hind legs. In severe cases there may be anemia, which will be evident as pale external mucous membranes. (Courtesy College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.19.4

### Cryptosporidiosis

*Cryptosporidium parvum* is a ubiquitous protozoan pathogen of mammals. Often waterborne, it is a significant cause of municipal water contamination. Although it causes a self-limiting infection in immunocompetent animals, the very young or immunocompromised individuals, such as AIDS patients, suffer from intractable diarrhea. When treating calves, veterinarians and veterinary students are at particular risk for infection. Cryptosporidia attach to surface epithelial cells of the stomach, small intestine, or colon. The protozoa displace the microvilli and are enclosed by surface cell membranes, but do not reside within a vacuole. Thus the parasite lives in a unique environment described as intracellular, but extracytoplasmic (Fig. 7-179). Microgametes, macrogametes, schizonts, trophozoites, meronts, merozoites, and oocysts can be demonstrated in the intestine adjacent to, or attached to, epithelial cells. Oocysts are 4 to 5  $\mu\text{m}$  in diameter and are shed in the feces. Recent studies have indicated that there are species-specific tropisms or biotypes of cryptosporidia. Previously, fecal contamination of water supplies by ruminants was believed to be the cause of most human outbreaks. Molecular typing of the organism has shown in many disease outbreaks that contamination with human feces causes human epidemics.

**Fig. 7-177 Fibrinonecrotic enteritis, small intestine, pig.**

Pseudomembranes are characteristic of porcine coccidiosis.

(Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Fig. 7-178 **Proliferative enteritis, small intestine, goat.** Coccidia-induced enterocyte hyperplasia results in nodule formation. Note the hyperplastic enterocytes lining crypts. H&E stain. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Oocysts can be identified in feces by Sheather's sucrose flotation and a modified acid-fast stain. Cryptosporidiosis causes subacute or chronic, sometimes bloody, watery diarrhea. There is associated dehydration and electrolyte loss. Although the disease can be fatal, particularly in the presence of other pathogens, it is often self-limiting in immunocompetent individuals. In these cases, the illness resolves spontaneously in about a week. Affected portions of the gastrointestinal tract are diffusely reddened and have fluid contents. The organisms appear as tiny blue (hematoxylinophilic) dots attached to the epithelial cells of affected segments. In addition to the dot forms, ring- and banana-shaped organisms are readily seen in Giemsa-stained sections. The lesions of enteritis or colitis consist of decreased mucosal (villous) height, irregular mucosal thickness, crypt necrosis, hyperemia, and an increase in lymphocytes and plasma cells in the lamina propria. Villous atrophy and fusion of the villi of the small intestine are the end result. Due to the intracellular, extracytoplasmic location of the parasite, chemotherapeutic intervention is ineffective. There are a few chemicals that can decontaminate the environment. Clorox, for example, is used experimentally to purify the parasites.

385

386

Fig. 7-179 **Cryptosporidiosis, small intestine.** **A**, Cow. Cryptosporidia (arrow) are attached to the microvillus border of the enterocyte membrane. Plastic-embedded, toluidine blue–stained section. **B**, Rabbit. The cryptosporidia form a trilaminated enveloping membrane upon fusion with the enterocyte membrane. Their location is thus intracellular, but extracytoplasmic. Microvilli are effaced. TEM. Uranyl acetate and lead citrate stain. (**A**, Courtesy Dr. A.R. Doster, University of Nebraska; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.19.5

### Giardiasis

Giardiasis has been reported in many species, including human beings, dogs, cats, horses, cattle, rabbits, guinea pigs, hamsters, rats, mice, chinchillas, and parakeets. In clinical veterinary practice, giardiasis is frequently recognized in puppies and kittens and causes concern among owners because of its zoonotic potential. Giardiasis is caused by a pear-shaped protozoan with posterior flagella, a ventral sucker, and four nuclei, two of which resemble eyes (Fig. 7-180). *Giardia lamblia* parasitizes the small intestine, particularly the duodenum. *Giardia* attach to the microvillous border of epithelial cells, producing membrane damage. Although generally asymptomatic, diarrhea may result in very young animals or in animals otherwise immunologically deficient.

**Fig. 7-180 Giardiasis, small intestine, dog.** A single pear-shaped flagellated protozoa is readily visible in the intestinal lumen (arrow). H&E stain. (Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

In large numbers, the parasites decrease the absorption of simple sugars and disaccharides secondary to microvillous destruction. Ingesta are then fermented by bacterial flora, creating gas and osmotically drawing water into the intestinal lumen. Clinical cases of giardiasis have brown, fluid diarrhea, abdominal discomfort without fever, weight loss, melena, and/or steatorrhea. The diagnosis is made by demonstrating *Giardia* in preparations of fresh feces or in histologic sections by identifying the organisms either with H&E or Giemsa stains.

7.2.9.19.6

### Ascariasis

Ascarids are easily recognized as proximal-intestinal, luminal nematodes that are smooth and white. They are round on cross section, thus giving them the appellation of roundworms together with the other nematodes. They vary greatly in length; the larger the host species, the larger the ascarids. They are 3 to 4 cm long in small animals and attain lengths of 40 to 50 cm in pigs and horses. Ascarids of domestic animals belong to the genera *Ascaris* (pigs), *Parascaris* (horses), and *Toxocara* (dogs, cats, and humans).

386

387

The young of these species acquire larval ascarids by intrauterine transmission during the last 7 to 10 days of gestation, through the milk of the dam, and later in life through parasite ova contamination of the environment. After ingestion, infective larvae penetrate the intestine and migrate to the liver via the portal circulation. From there the larvae migrate via the caudal vena cava to the lungs. After leaving the circulation and entering the alveoli, the larvae undergo development, and are coughed into the pharynx and swallowed. Development to adults occurs in the intestine. Ova passed in the feces complete the life cycle.

Alternatively, *Toxascaris leonia* of canids and felids is ingested via an intermediate host.

Hepatopulmonary migration does not occur. Lesions produced by ascarid larval migration include canine multifocal eosinophilic gastroenteritis and visceral larval migrans. Animals affected with heavy ascarid burdens lose weight, grow poorly as a result of competition for nutrients between luminal parasites and the host, and often have a pear-shaped abdomen when held vertically. Adult worms may be vomited or passed in the diarrheic feces. A hacking cough termed “thumping” is a sign of pulmonary larva migrans, especially in pigs. Anthelmintic administration can cause a rapid die off of adult ascarids, resulting in intestinal occlusion. Ascarids continue to migrate after the death of the host and may be found in aberrant locations such as the bile duct, stomach, oral cavity, pancreatic duct, and abdomen (Fig. 7-181).

7.2.9.19.7

### Hookworm Disease

Parasitism by hookworms varies from asymptomatic to fatal based on the challenge dose of parasites, the host's age, nutritional status, and likely its immunologic state. Death, when it occurs, is by exsanguination because hookworms are blood eaters (Fig. 7-182). Challenge dosage is often exacerbated by poor nutritional and sanitary conditions, mild climatic conditions, and moisture. Hookworms are generally small nematodes, 1 to 1.5 cm long. Their habitat is usually the proximal small intestine. Genera include *Ancylostoma* and *Uncinaria* in dogs, *Bunostomum* in ruminants, *Globocephalus* in pigs, and *Ancylostoma* and *Necator* in humans. *Ancylostoma caninum* in dogs has zoonotic potential. Environmental contamination occurs from the large number of eggs produced in the intestine. The first-through third-stage larvae feed on environmental bacteria. Third-stage larvae are infective and enter the host either by ingestion or direct dermal penetration. From either point of entry, they migrate through the pulmonary system, through somatic tissue to the uterus, or through mucosal tissue. Larvae may also be present in colostrum. The final destination is the intestine, where eggs are produced, completing the life cycle.

**Fig. 7-181 Fibrinous peritonitis, abdomen, pig.** The presence of fibrin along with ascarids in this pig's abdomen indicates that the intestinal rupture occurred antemortem. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 7-182 Hookworms, hemorrhagic enteritis, small intestine, dog.** Where hookworms have detached, hemorrhage is present. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

Because prenatal infections with hookworms do not become patent for 11 days, fecal examinations may be negative. Otherwise, fecal examination, especially in young animals with anemia is diagnostic of this disease. Adult hookworms bury into the villous, ingesting tissue, mucus, and blood ([Fig. 7-183](#)). When the worm moves to another attachment site, blood may continue to flow from the wound for 30 minutes.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.19.8

### Trichuriasis

Trichurids, or whipworms, are long and slender at their anterior ends and may be numerous within the cecum and colon. Trichurids have a direct life cycle. The name *Trichuris* translates to “whip-tail,” which is a misnomer because the parasite actually has a “whip-head” that invades and attaches to the mucosa of the cecum, colon, and rectum. Although the parasite ingests blood, anemia is rarely a clinical symptom. Bloody diarrhea may be present. Different species are parasites of carnivores, ruminants, pigs, and humans. The disease in each species is similar. The horse does not have a whipworm.

387

388

**Fig. 7-183 Hookworm enteritis, intestine, dog.** A hookworm has burrowed deep into and attached to the mucosa. H&E stain. (Courtesy College of Veterinary Medicine, Cornell University.)

*Trichuris* eggs are elongate, or football-shaped, with an operculum at either end, and are very resistant to environmental conditions. Most infections are asymptomatic and the complete life cycle may take up to 3 months. Therefore repeated dewormings are necessary to eliminate infection, even in the absence of fecal ova. Symptoms may be vague, with only paroxysmal diarrhea. Gross enteric lesions vary from mild to erosive and ulcerative.

## Pathologic Basis of Veterinary Disease, 4th Edition

7.2.9.19.9

### Strongyloidosis

*Strongyloides* spp. are unique in having free-living and parasitic forms. Rhabditiform larvae may develop parthenogenetically. Free-living parasites are both male and female and undergo sexual reproduction. Enteritis can be severe; larvae or larvated eggs are in the feces of infected animals.

*Strongyloides stercoralis* of dogs is zoonotic. *Strongyloides* spp. also infect horses, pigs, and cats. Geographic differences in parasite populations account for differences in virulence within host species. Hyperinfection and autoinfection may occur, adding to the parasite burden. Larvae may enter the host by skin penetration, or less often by ingestion. *Strongyloides* spp. infection may be acquired in utero and through colostrum and milk. Larvae migrate to the blood stream and lungs. When they gain access to alveoli, they subsequently migrate to airways, where they are carried, via the mucociliary elevator, to the pharyngeal cavity and are swallowed. Small intestinal parasitism is characterized by larvae residing within superficial mucosa (Fig. 7-184). Epithelial destruction by the parasites may result in villous atrophy and crypt hyperplasia. The nonspecific clinical signs include diarrhea, hypoproteinemia, weight loss, and dehydration. Rhabditiform dermatitis may also occur.

**Fig. 7-184 Strongyloidosis, small intestine, horse.** Cross sections of the parasite (*Strongyloides westeri*) are present in the superficial mucosa. Note the mild chronic inflammatory response with some eosinophils in the lamina propria. H&E stain. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

7.2.9.19.10

### Trichostrongylosis

Trichostrongyles are small nematodes that parasitize the small intestine of ruminants. Mild climates promote clinical disease. These parasites have a direct life cycle. Third-stage larvae are rendered infective in the acid environment of the abomasum. The larvae burrow in between crypt enterocytes, but do not generally penetrate the basement membrane. Paradoxically, crypt hyperplasia is followed by villous atrophy. As with most other parasitisms, crowding, poor sanitation, and inadequate nutrition potentiate

## Pathologic Basis of Veterinary Disease, 4th Edition

---

disease. Protein leakage into the intestinal lumen together with absorptive enterocyte loss leads to diarrhea, cachexia, and its metabolic consequences, which can be severe and widespread through many organ systems.

### 7.2.9.19.11 Nematodirosis

*Nematodirus* nematodes are parasites of the cranial small intestine of ruminants. The life cycle is direct. 388

Unlike the case with other strongyles, *Nematodirus* larvae within ova are resistant to cold temperatures. In fact, the ova must overwinter to be infective. This is evolutionally interesting because it allows for a new crop of susceptible hosts, particularly lambs and calves each year. Fourth- and fifth-stage larvae reside in deeper layers of the mucosa than do the trichostrongyles. Villous atrophy of the cranial small intestine is the predominant histologic lesion. *Nematodirus* spp. do not generally cause disease except in association with other parasites. Signs include green diarrhea, weight loss, and hypoproteinemia secondary to weight loss and inappetence. 389

### 7.2.9.19.12 Cooperiosis

Also a small intestinal parasite of ruminants, *Cooperia* nematodes—unlike other trichostrongyles—do not burrow into the intestine. Rather, they reside between villi, causing pressure necrosis. Their life cycle and clinical signs are similar to that of the other strongyles already described.

### 7.2.9.19.13 Oesophagostomum

The nodular worms of ruminants (*Oesophagostomum columbianum*, *Oesophagostomum radiatum*) and pigs (*Oesophagostomum dentatum*) cause subserosal mineralized nodules that are characteristic of the disease. These nodules generally are of no clinical significance, but they make the intestines unsuitable for use as sausage casings. Occasionally, they are associated with, and can be the cause of, intussusceptions.

Third-stage larvae of *Oesophagostomum columbianum* of sheep are ingested, penetrate deeply into the small intestinal wall, excyst, and molt to fourth-stage larvae, which mature in the colon. They may encyst in the colonic wall and become mineralized subserosal nodules or may mature to adults. Disease is more severe in nutritionally debilitated animals. Most infestations are asymptomatic. *Oesophagostomum radiatum* of cattle may produce inappetence, hypoproteinemia from damaged enterocyte tight junctions, and anemia and hemorrhage from consumptive coagulopathy induced by the parasites. Nodules may also form, as in sheep. Oesophagostomiasis in pigs is usually asymptomatic, although ill thrift and malaise secondary to typhlocolitis may occur.

### 7.2.9.19.14 Pinworms

*Oxyuris equi* is the most common pinworm of domestic animals. The parasites occupy the lumen of the distal intestine of horses and occasionally cause rectal pruritus by laying their eggs on the perineal region. *Enterobius vermicularis* is the pinworm of primates and great apes. It is not zoonotic and is generally of little clinical consequence.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 7.2.9.19.15 Cestodes

Tapeworms, although frequently found in the alimentary system, are generally of little clinical significance. They require two and sometimes three hosts to complete their life cycles. Tapeworms attach to the gut wall by means of their anterior scolex, which may have hooks in addition to four suckers (Fig. 7-185). Although they can cause some damage at the site of attachment, generally they compete with the host for nutrients. Lacking an alimentary system, they absorb nutrients through their surface. Tapeworms are flat, segmented, and hermaphroditic, reproducing by addition of segments or proglottids. Examples of tapeworms are *Anoplocephala* spp. in horses, *Moniezia* spp. in ruminants, and *Diphylobothrium* and *Dipylidium* spp. in dogs and cats. *Mesocystoides* spp. can infect dogs. In some cases, this parasite can perforate through the intestine and proliferate in the peritoneal cavity.

**Fig. 7-185 Cestodiasis, small intestine, fur seal.** Segmented tapeworms are present in this otherwise normal intestine. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

*Taenia* and *Echinococcus* spp. are the most destructive of the cestodes. Although carnivores are the definitive hosts, the larval forms reside in the viscera and body cavities of the intermediate hosts, usually ruminants, pigs, horses, or rodents. Human beings can also become infected, sometimes taking 20 or 30 years for clinical disease to appear. The damage in the intermediate hosts may be quite severe.

### 7.2.9.19.16 Trematodes

Trematodes are uncommon parasites of the alimentary tract. *Nanophyetus salmincola* uses a snail and a fish as intermediate hosts. It carries the rickettsia responsible for salmon poisoning in the Northwestern United States. Lesions of the intestine are hemorrhagic enteritis.

*Alaria* spp. can attach to the small intestine of dogs and cats, but are generally innocuous. The mesocercariae can cause tissue damage during their migrations through body organs of the host. Paratenic hosts are frogs, snakes, and mice.

## Pathologic Basis of Veterinary Disease, 4th Edition

Schistosomiasis of ruminants, pigs, horses, and dogs can cause granulomatous intestinal lesions with protein loss secondary to the parasite's presence in mesenteric veins after migration through the liver. Parasites are acquired by direct penetration of the skin by cercariae.

389

390

7.2.9.19.17

### Acanthocephalans

The thorny-headed worm of pigs, *Macracanthorhynchus hirudinaceus*, is a small-intestinal parasite with an arthropod intermediate host. They are occasionally misidentified as tapeworms, which they superficially resemble. However, they are not truly segmented parasites. They occasionally penetrate the bowel wall at the site of parasite attachment, causing peritonitis.

*Prosthenorchis* spp. are acanthocephalids of primates. Cockroaches are the intermediate hosts.

7.2.9.20

### INTESTINAL NEOPLASIA

Neoplasms of various types occur in the gastrointestinal system of domestic animals. Those of the oral cavity and stomach have already been discussed. Intestinal neoplasms are diagnosed most frequently in dogs and cats, in large part because of their longer life span. Additionally, pets live in close harmony with their human companions, and thus it is possible that some of the same environmental factors that cause human cancer may also cause similar problems in animals.

In dogs, benign neoplasms of the intestinal tract are most commonly adenomas or polyps, and their malignant counterparts adenocarcinomas. Smooth muscle neoplasms termed leiomyomas and leiomyosarcomas arise from existing intestinal muscular layers. Lymphosarcoma can be solitary, metastatic, or multicentric. In cats, the most common neoplasms include alimentary lymphosarcoma (Fig. 7-186); mastocytomas (Fig. 7-187), which are associated with ulceration; adenomas; adenocarcinomas; and carcinoids. In canids, 5% to 7% of lymphomas are gastrointestinal. Those of the gastrointestinal tract are epitheliotropic and primarily T lymphocyte in origin. In humans, most gastrointestinal lymphomas are of B-cell origin. In sheep, adenocarcinomas of the intestine are fairly common and are virus-induced. In cows, alimentary lymphosarcoma is most common. Horses rarely have intestinal neoplasms develop.

**Fig. 7-186 Lymphoma (lymphosarcoma), colon, cat.** Numerous submucosal nodules contain neoplastic lymphocytes. Note that the mucosal epithelium is intact (smooth and shiny) and not ulcerated.

## 8 Chapter 8 Liver, Biliary System, and Exocrine Pancreas\*

JOHN M. CULLEN

### 8.1 INTRODUCTION

#### 8.1.1 LIVER AND BILIARY SYSTEM

##### 8.1.1.1 NORMAL ANATOMY

###### 8.1.1.1.1 Development

Early in embryogenesis, the origins of the liver are evident. The hepatic diverticulum, also termed the liver bud, arises from embryonic endoderm as a hollow out-pouching of the primitive duodenum. Primitive hepatic epithelial cells of the hepatic diverticulum extend into the adjacent mesenchymal stroma and surround the vessels that form the vitelline venous plexus, a complex of vessels that drain the yolk sac. This relationship between the epithelial cells of the liver and the small-caliber vitelline vessels is the earliest developmental form of the hepatic sinusoids. The caudal part of the hepatic diverticulum will develop into the gallbladder and the cystic duct. Hepatic connective tissue is derived from the septum transversum, a sheet of cells that incompletely separates the pericardial and peritoneal cavity, and an ingrowth of mesenchymal cells from the coelomic cavity.

The biliary epithelium also arises from the hepatic diverticulum. Intrahepatic ducts develop from a structure, termed the limiting plate, which is composed of hepatoblasts that surround the portal vein branches and ensheath the mesenchyme of the primitive portal tract. A second discontinuous outer layer of primitive hepatoblasts forms subsequently, and the two-cell thick regions remodel into tubules and become the intrahepatic biliary ductular system. Development of the ducts begins at the porta hepatis and extends to the margins of the liver until the later stages of gestation. The residual portion of the hollow outpouching of the hepatic diverticulum persists to become the extrahepatic bile ducts.

It is known that the hepatocytes and the biliary epithelial cells share a common embryonic origin, but the factors that lead to the final characteristic morphology of the primitive hepatoblasts are not well understood. Epithelial-mesenchymal interactions are believed to play a role. Primitive hepatic epithelial cells in contact with vascular endothelium are destined to become hepatocytes, and those in contact with the developing mesenchyme of the portal tracts develop into bile ducts.

\* Previous contributions to this chapter were authored by Dr. N. J. MacLachlan, School of Veterinary Medicine, University of California-Davis.

###### 8.1.1.1.2 Structure

The liver is the largest internal organ in the body. In adult carnivores, the liver constitutes 3% to 4% of the body weight. In adult omnivores, it is about 2% of body weight and about 1% of the body weight in herbivores. In the neonate of all species, the liver is a larger percentage of body weight than in the adult. In monogastric animals, the liver abuts the diaphragm and occupies the central area of the cranial abdomen. In ruminants the liver is displaced to the right side of the cranial abdominal cavity. A series of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

ligaments maintain the liver in its position. The coronary ligament attaches the liver to the diaphragm near the esophagus. The falciform ligament attaches the midline of the liver to the ventral midline of the abdomen. The round ligament, a remnant of the umbilical vein, is embedded within the falciform ligament. The liver is supplied with blood from two sources. The portal vein drains the digestive tract and provides 60% to 70% of the total afferent hepatic blood flow. The hepatic artery provides the remainder of hepatic blood flow. Blood leaves the liver via the hepatic vein, which is very short, and enters the caudal vena cava. The liver has a smooth capsular surface and the parenchyma consists of friable red-brown tissue that is divided into lobes. Gross subdivision of the liver into lobes differs among the domestic species. At the periphery, the lobes taper to a sharp edge.

393

395

**Fig. 8-1 Schematic views of the microscopic and functional organization of the liver.** **A**, Microscopic organization of the liver. A central vein is located in the center of the lobule with plates of hepatocytes arranged radially. Branches of the portal vein and hepatic artery are located on the periphery of the lobule, and blood from both perfuses the sinusoids. Peripherally located bile ducts drain the bile canaliculi that run between hepatocytes. **B**, Functional organization of the liver. Both the lobule and the acinus are represented. The lobule is a hexagonal unit with portal areas at the margin and a terminal hepatic vein (central vein) at the center. The lobule is divided into the periportal, midzonal, and centrilobular areas. The acinus is a diamond-shaped structure with the distributing branches of the vessels from the portal areas as the center of the structure. Zone 1 of the acinus is closest to the afferent blood supply, and zone 3 is at the tip of the diamond-shaped structure, close to the terminal hepatic vein. Zone 2 is between zones 1 and 3. (**A**, From McCance KL, Huether SE: Pathophysiology: the biologic basis for diseases in adults and children, ed 4, Mosby, 2002, St Louis. **B**, From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

The classical functional subunit of the liver is the hepatic lobule, a hexagonal structure, 1 to 2 mm wide. At the center, the lobule has a central vein (also termed the terminal hepatic venule), which is a tributary of the hepatic vein, and at the angles of the hexagon, it has portal tracts (Fig. 8-1). The portal tracts contain bile ducts, branches of the portal vein, the hepatic artery, nerves, and lymph vessels, all supported by a collagenous stroma (Fig. 8-2). The limiting plate, a discontinuous border of hepatocytes, forms the outer boundary of the portal tract. Blood flows into the sinusoids from the terminal distributing branches of the hepatic artery and portal veins that leave the portal tracts and form an outer perimeter of the lobule

395

396

## Pathologic Basis of Veterinary Disease, 4th Edition

(Fig. 8-2). Portal blood and hepatic arterial blood mix in the sinusoids. Blood drains from the sinusoids into the central veins and to progressively larger sublobular veins and then into the hepatic veins.

**Fig. 8-2 Liver, hepatic lobules, normal dog.** **A**, Low magnification. A central vein (C) is located in the center of the lobule. Branches of the portal vein, hepatic artery, bile duct, and lymphatic vessels are located on the periphery of the lobule in portal tracts (P) (also Fig. 8-2, C). H&E stain. **B**, Higher magnification. Plates of hepatocytes arranged radially between a central vein (C) to portal tracts (P). H&E stain. **C**, Higher magnification, portal tract. The normal portal tract contains the hepatic artery (HA), bile duct (BD), portal vein (PV), and several lymphatic vessels (LV). These structures are surrounded by a collagenous extracellular matrix that forms an abrupt border with a circumferential row of hepatocytes, termed the limiting plate (LP—dotted line). Note that the profile of the portal vein is typically larger than those of the hepatic artery and bile duct. H&E stain. (**A** and **C**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University. **B**, Courtesy Dr. J.F. Zachary, College of Veterinary Medicine, University of Illinois.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Alternatively, when the liver is viewed as a bile-secreting gland, the acinus is the anatomic subunit of the hepatic parenchyma. Terminal afferent branches (penetrating vessels) of the portal vein and hepatic artery project into the parenchyma, like branches from the trunk of a tree, forming the long axis of the diamond-shaped acinus. Thus terminal afferent branches of the portal vein and hepatic artery are at the center of the acinus and the terminal hepatic venule is located at the periphery. Each terminal hepatic venule (central vein) receives blood from several acini. There are three zones within the acinus. Zone 1 is closest to the afferent blood coming from the hepatic artery and the portal vein. Zone 2 is peripheral to zone 1, and zone 3 borders the terminal hepatic venule (Fig. 8-1). In this anatomic unit, bile flows from the hepatocytes through the bile canaliculi in zone 3 into the bile ductules at the termination of zone 1 at the portal area and then into bile ducts in the portal areas.

**Fig. 8-3 Hepatocyte, ultrastructure, liver, normal dog.** **A**, Features to note are the nucleus (*N*), mitochondria (*M*), secondary lysosomes (*2L*), glycogen (*G*), rough endoplasmic reticulum (*RER*), Golgi (*arrow*), bile canaliculus (*BC*), and free ribosomes (*R*). Note desmosomes on both sides of the bile canaliculus (*arrowheads*). TEM. Uranyl citrate and lead acetate stain. **B**, Higher magnification of bile canaliculus (*BC*). Note the microvilli projecting into the lumen of the canaliculus. TCM Uranyl citrate and lead acetate stain. (**A** and **B**, Courtesy Dr. V. Meador, Eli Lilly Co.)

**Fig. 8-4 Schematic diagram of the hepatic sinusoid.** The vascular lumen is lined by discontinuous capillaries. Kupffer cells rest on the endothelial cells and project into the sinusoid. Between the endothelial cells and the hepatocytes is a gap called the space of Disse. Microvilli extending from the luminal aspect of the hepatocytes are found in this space. Hepatic stellate cells are situated within the space of Disse and extend between hepatocytes. (Schematic based on concepts presented in Friedman SL: *J Biol Chem* 275:2247-2250, 2000; and Crawford JM: *Curr Op Gastroenterol* 13:175-185, 1997.)

The ultrastructural appearance of hepatocytes reflects the cell's active metabolism, bile secretion, and close contact with the plasma (Fig. 8-3). The surface of the hepatocyte that faces the lumen of the sinusoids contains an abundance of microvilli, which increase the hepatocytic surface area and facilitate uptake of plasma-borne substances, such as bilirubin and amino acids, and the secretion of products of hepatic metabolism, such as lipoproteins and clotting factors. Basolateral aspects of hepatocytes are characterized by the presence of canaliculi, modified portions of the cell membrane in two adjacent hepatocytes, which form a lumen for bile secretion. The cytoplasm contains glycogen and a variety of organelles, including numerous mitochondria, lysosomes, and abundant smooth and rough endoplasmic reticulum.

Within the liver, hepatocytes are arranged in one-cell thick branching plates, which extend radially from the terminal hepatic venule. Hepatic plates are separated by vascular sinusoids. Blood from the terminal

396

397

## Pathologic Basis of Veterinary Disease, 4th Edition

afferent branches of the hepatic artery and portal vein mixes in the hepatic sinusoids and flows to the terminal hepatic venule. Hepatic sinusoids differ from capillaries in that they are lined by discontinuous capillaries that lack a typical basement membrane (Fig. 8-4), whereas capillaries have a continuous endothelial lining and are ensheathed in the basement membrane. The sinusoids are critical for appropriate hepatic function. The architecture of the sinusoids enables efficient uptake of plasma constituents by hepatocytes and facilitates hepatocellular secretion. A fine scaffold of electron lucent basement membrane that contains collagen types III, IV, and XVIII, and other extracellular matrix components supports the sinusoidal endothelial cells (Figs. 8-4 and 8-5). These elements collectively make up the “reticulin” of the liver (Fig. 8-6).

**Fig. 8-5 Hepatic sinusoids, liver, normal dog.** A sinusoid containing erythrocytes (*E*) can be seen in the upper right-hand portion of the figure. The margins of the sinusoid are lined with discontinuous capillaries (*arrowheads*). The space of Disse (*double-headed arrows*) lies between the endothelial cells and the hepatocytes. Microvilli (*MV*) project from the hepatocytes into the space of Disse. Rough endoplasmic reticulum (*RER*) and lipid droplets (*L*) can be seen in the hepatocyte cytoplasm. TEM. Uranyl citrate and lead acetate stain. (Courtesy Dr. V. Meador, Eli Lilly Co.)

**Fig. 8-6 Reticulin fibers (reticulin stain), hepatic extracellular matrix, liver, normal dog.** This stain reveals “reticulin” (*black*), composed of extracellular matrix and the type 3 collagen found within the space of Disse that forms the scaffolding of the hepatic parenchyma. Note the radial arrangements of the hepatic plates and the single hepatocyte thickness of the plates. A central vein is evident in the center of the image. Gordon and Sweet's reticulum stain with a nuclear fast red counterstain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Although blood cells are normally excluded from the space of Disse because they are too large to pass through endothelial gaps, the modified endothelial cells and basement membrane permit plasma to pass freely into a gap between the endothelial cells and the hepatocytes (Fig. 8-4). This critical anatomic feature of the liver is termed the space of Disse. Within this space, plasma constituents come into contact with the luminal surface of the hepatocytes. This surface of the hepatocytes is characterized by the presence of numerous microvilli, which increase the surface area of the hepatocytes and facilitate uptake of a variety of plasma-borne substances, as well secretion of synthesized products. Any damage to this area has significant impact on hepatic function.

The lumen of the sinusoids contains hepatic macrophages, termed Kupffer cells (Fig. 8-7). These cells are members of the monocyte-macrophage system, and they clear infectious agents and senescent cells, such as erythrocytes, particulate material, endotoxin, and other substances from the sinusoidal blood. They are mobile and able to migrate along the sinusoids and into areas of tissue injury and regional lymph nodes. Kupffer cells are involved in cytokine-driven interactions with hepatocytes, endothelial cells, and the stellate cells discussed later. They can express class II histocompatibility antigens and function as antigen-presenting cells, although they are not as efficient as the macrophages in other tissue. Phagocytosis and clearance of immune complexes are the primary roles of Kupffer cells. Kupffer cells are derived from in situ replication and recruitment of blood-borne monocytes.

397

398

Bundles of collagen (*C*) are found at the margins of the cells. Erythrocytes (*E*) are within the sinusoidal lumen. TEM. Uranyl citrate and lead acetate stain. (Courtesy Dr. V. Meador, Eli Lilly Co.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Hepatic stellate cells (also termed lipocytes or Ito cells) are found within the space of Disse and between hepatocytes at the edge of the space of Disse (Fig. 8-8). Normally, hepatic stellate cells are primarily responsible for storing vitamin A in their characteristic cytoplasmic vacuoles. During hepatic injury, hepatic stellate cells alter their morphology and their function. These activated hepatic stellate cells lose their vitamin A content and synthesize collagen and other extracellular matrix components that lead to hepatic fibrosis.

Bile flows within the lobule in the opposite direction to blood flow, which facilitates the concentration of bile. The biliary system commences as canaliculi within the centrilobular (periacinar) areas of the hepatic lobule. The walls of canaliculi are formed entirely by the cell membranes of adjacent hepatocytes. Just outside the limiting plate, canaliculi drain into cholangioles (also known as the canals of Hering) that are lined by low cuboidal epithelium. The cholangioles converge into interlobular bile ducts that are lined with cuboidal epithelium and located in the portal areas. Bile then flows into the right and left hepatic ducts that unite to form the hepatic duct. The confluence of the common hepatic duct and the cystic duct from the gallbladder form the common bile duct by which bile is carried to the duodenum. The gallbladder is responsible for storage and concentration of bile in most species. It is absent in the horse and rat.

Both sympathetic and parasympathetic nerves running along the portal vein and the hepatic artery innervate the liver. The nerve fibers enter the liver at the hilus and ramify to the level of the portal tracts and then extend along the sinusoids. Nerve supply is believed to affect sinusoidal blood flow, the balance of hepatic blood flow from the portal vein and the hepatic artery, and metabolic functions of the liver.

8.1.1.1.3

### Normal Function

The liver performs many critical functions, including the following:

- Bilirubin metabolism
- Bile acid metabolism
- Carbohydrate metabolism
- Lipid metabolism
- Xenobiotic metabolism
- Protein synthesis
- Immune function

8.1.1.1.3.1

### Bilirubin metabolism

Excretion of bile is the main exocrine function of the liver. Bile is composed of water, cholesterol, bile acids, bilirubin, inorganic ions, and other constituents. Bile formation is continuous, but the rate of secretion can vary significantly. There are three major purposes for bile synthesis. The first purpose is excretory; many of the body's waste products, such as surplus cholesterol, bilirubin, and metabolized xenobiotics are eliminated in bile. The second purpose is the facilitation of digestion; bile acids

## Pathologic Basis of Veterinary Disease, 4th Edition

---

secreted into the intestine aid in the digestion of lipids within the intestine. The third is to provide buffers to neutralize the acid pH of the ingesta.

Bilirubin, a major component of bile, is produced from the metabolic degradation of hemoglobin, and to a lesser extent, other heme proteins including myoglobin and the hepatic hemoproteins, such as cytochromes (Fig. 8-9). The majority of bilirubin is derived from normal extrahepatic breakdown of senescent erythrocytes in cells of the monocyte-macrophage phagocytic cell series. Senescent erythrocytes normally are phagocytosed by macrophages of the spleen, bone marrow, and liver. Within the phagocyte, the globin portion is degraded and the constituents are returned to the amino acid pool.

The heme iron is transferred to iron-binding proteins such as transferrin for recycling. The remaining 398

portion of heme is first oxidized by heme oxygenase to biliverdin. In the next metabolic step, biliverdin reductase converts biliverdin to bilirubin. Subsequently the bilirubin, which is poorly soluble in an aqueous medium, is then released into the blood in its unconjugated form and bound to albumin to increase its solubility in plasma. 399

**Fig. 8-9 Schematic diagram of bilirubin metabolism and elimination (as depicted in human beings).** 1, Normal bilirubin production from heme (0.2 to 0.3 g per day) is derived primarily from the breakdown of senescent circulating erythrocytes, with a minor contribution from degradation of tissue heme-containing proteins. 2, Extrahepatic bilirubin is bound to serum albumin and delivered to the liver. 3, Hepatocellular uptake and 4, glucuronidation in the endoplasmic reticulum generate bilirubin monoglucuronides and diglucuronides, which are water soluble and readily excreted into bile. 5, Gut bacteria deconjugate the bilirubin and degrade it to colorless urobilinogens. The urobilinogens and the residue of intact pigments are excreted in the feces, with some reabsorption and excretion into urine. (From Kumar V, Abbas AK, Fausto N: Robbins & Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The process of bilirubin elimination can be divided into three phases: uptake, conjugation, and secretion. Uptake refers to the process by which hepatocytes remove the bilirubin bound to albumin from the circulation. Unconjugated bilirubin is separated from albumin at the sinusoidal surface and bilirubin is taken up by hepatocytes by a carrier-mediated process. In the second phase of bilirubin metabolism, bilirubin is conjugated, principally with glucuronic acid, by bilirubin UDP-glucuronyltransferase in the endoplasmic reticulum. Following conjugation, bilirubin becomes water soluble and less toxic. It is then excreted, in the third phase of bilirubin metabolism, into the bile by active transport through specialized portions of hepatocyte membranes that form the margins of the bile canaliculi. The excretion phase is the rate-limiting step in most species.

Within the gastrointestinal tract, conjugated bilirubin is converted to urobilinogen by bacteria and a fraction of this is reabsorbed into the portal blood, a process called enterohepatic circulation, and returned to the liver. The majority of urobilinogen that is absorbed from the gastrointestinal tract is resecreted into bile. Urobilinogen has a small molecular weight and is freely filtered through the glomerulus, and small amounts are normally found in the urine. Urobilinogen that is not absorbed from the intestine becomes oxidized to stercobilin, which is responsible for the color of the feces.

### 8.1.1.1.3.2

#### Bile acid metabolism

The three principal functions of bile acids, important constituents of bile, are maintenance of cholesterol homeostasis, stimulation of bile flow and digestion, and absorption of fats and fat-soluble vitamins. Bile acids are synthesized in the liver from cholesterol and are conjugated to glycine or taurine to facilitate their interaction with other components of bile and to prevent precipitation into calculi when they are secreted into the bile. The major bile acids are cholic acid and cheno-deoxycholic acid, but there are various types and proportions of bile acids found in different species. Bile acids are actively secreted into the bile canaliculi from the hepatocyte cytoplasm by specific intramembranous molecular pumps against a concentration gradient, which creates an osmotic gradient, stimulating the inflow of water and solutes into the bile canaliculi. Conjugated bile acids are, therefore, the principal physiologic stimulus for bile production through a process termed bile acid-dependent flow. Bile acids are effective detergents that assist in the digestion of lipids within the intestine, and increasing the solubility of lipids secreted into the bile. The quantities of bile acids required far exceed the liver's capacity to produce them. For this reason, bile acids are avidly reabsorbed from the ileum, extracted from the portal blood, and resecreted into bile via a process known as enterohepatic circulation. This is a very efficient system. As much as 95% of secreted bile acids are recycled, and the proportion of reabsorbed bile acids in the liver greatly exceeds that of recently synthesized bile acids; bile acids may be recycled 15 times a day. Interruption of this process results in fat malabsorption and a deficiency of fat-soluble vitamins.

399

400

### 8.1.1.1.3.3

#### Carbohydrate metabolism

The liver has an important role in the regulation of plasma glucose concentrations. After eating, the liver removes carbohydrates (i.e., glucose, fructose) from the plasma and stores them as glycogen or fatty acids. In periods of need, energy balance is maintained by glycolysis of stored glycogen or by gluconeogenesis. Production of energy by oxidative phosphorylation and  $\beta$ -oxidation of fatty acids in hepatic mitochondria is used to sustain the activities of the hepatocyte.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.1.3.4

### Lipid metabolism

The liver plays a central role in lipid metabolism. It is involved in the production and degradation of plasma lipids, such as cholesterol, triglycerides, phospholipids, and lipoproteins. Cholesterol is synthesized, secreted, and degraded by hepatocytes. Hepatocytes can synthesize fatty acids when energy levels are high, and they can oxidize fatty acids as an energy source when necessary.

8.1.1.1.3.5

### Xenobiotic metabolism

Foreign substances (xenobiotics), such as many therapeutic drugs, insecticides, and endogenous substances—such as steroids that are lipophilic—require conversion to water-soluble forms for elimination from the body. The cytochrome p450 enzymes of the smooth endoplasmic reticulum of the hepatocytes serve as the major site of metabolism of these substances in preparation for excretion in bile or urine. This process is discussed in detail in the section on toxic liver injury.

8.1.1.1.3.6

### Protein synthesis

Synthesis of the majority of plasma proteins, mainly within the rough endoplasmic reticulum, is a principal function of the liver. Proteins produced in the liver include plasma proteins, such as albumin; a variety of transport proteins; lipoproteins; clotting factors II, V, and VII-XIII; fibrinolysis proteins; some acute phase proteins; and components of the complement system. The liver is responsible for synthesis of approximately 15% of body proteins.

The liver is also the principal site of ammonia metabolism. Highly toxic ammonia is generated through catabolism of amino acids. Metabolic conversion of ammonia into urea, a far less toxic compound, occurs through the urea cycle, which occurs almost exclusively in the liver.

8.1.1.1.3.7

### Immune function

The liver has a significant immune function. It is involved in systemic, local, and mucosal immunity. It participates in the response to systemic inflammation through the synthesis and release of acute phase proteins. It contains, perhaps, the largest pool of mononuclear phagocytes and natural killer cells in the body in most species. The Kupffer cells lining the sinusoids provide the first line of defense against infectious agents, endotoxin, and foreign material absorbed from the intestines before they gain access to the systemic circulation. Most blood-borne foreign material is cleared by Kupffer cells in all domestic species, except members of the family Artiodactyla (pigs, goats, and cattle), in which this function is performed by intravascular macrophages in the pulmonary alveolar capillaries. The liver is also involved in transport from plasma cells and recirculation of secretory immunoglobulin A (IgA), the primary immunoglobulin of the mucosal surfaces, into the biliary tree and intestine.

8.1.1.2

## HEPATOBIILIARY INJURY AND DEGENERATION

8.1.1.2.1

### Portals of Entry

The liver and biliary systems are exposed to infectious or otherwise injurious substances via three main routes: hematogenous, biliary, and direct penetration ([Box 8-1](#)). The liver receives the entire flow of the

## Pathologic Basis of Veterinary Disease, 4th Edition

portal vein and as a consequence is bathed in potentially injurious microbes, which inhabit and penetrate the digestive system, and toxic substances that have been ingested or produced by the intestinal flora. The distribution of blood from the portal vein to the different lobes of the liver is most likely nonuniform.

400

401

So-called portal streaming refers to the differential flow of portal blood from one segment of the digestive tract to particular lobes of the liver. This explains why some lobes of the liver are more severely affected by toxins that are absorbed by the small intestine rather than the large intestine. Examples of this include the preponderance of injury to the left liver lobe of sheep that ingest the mycotoxin sporidesmin. Systemic infections or intoxications can also affect the liver through the blood from the hepatic artery. Neonates and fetal animals are also at risk from infections ascending the umbilical vein. Infectious agents, such as enteric bacteria and parasites, can also gain access to the liver through the biliary tree that is in direct connection with the duodenum and enteric bacteria. Finally, direct penetration of the body cavity or from the digestive tract (i.e., traumatic reticuloperitonitis or foreign bodies in the reticulum) can deliver infectious or traumatic insults.

### 8.1.1.2.2

#### Defenses

The liver is well defended from blood-borne injury by the Kupffer cells, the fixed macrophages that are distributed intermittently throughout the lumen of the sinusoids on the surface of endothelial cells (Box 8-2). They actively ingest and degrade bacteria and other organisms, senescent cells such as erythrocytes and particulate matter in the sinusoidal blood. They are very efficient and are able to clear virtually all particulate matter in a single pass through the liver. Kupffer cells are particularly important in the removal of endotoxin from the portal blood.

The biliary tree, like the upper gastrointestinal tract, is defended from infection by secreted IgA as part of mucosal immunity (Box 8-2). The majority of biliary IgA is synthesized by gastrointestinal plasma cells. The majority of released IgA is taken into lymph and from there it enters the blood stream. Hepatocytes in many species can transport IgA from blood across their cell membranes via a secretory component-mediated endocytosis. Subsequently, IgA molecules reach the bile by secretion into canaliculi. Concentrations of bile IgA are maintained by enterohepatic circulation. Within the biliary tree, IgA provides defense from infectious agents and clearance of harmful antigens as antibody-antigen complexes.

## Pathologic Basis of Veterinary Disease, 4th Edition

In addition, the biliary tree is protected by the sphincter at the terminal end of the common bile duct, which provides a physical barrier to the ascent of enteric bacteria and the continuous flow of bile that assists in flushing bacteria out of the ducts.

The liver is protected from direct penetration by its anatomic location within the protection of the rib cage. The wall of the digestive tract also provides a certain degree of protection from penetration by ingested foreign bodies.

The high metabolic rate of hepatocytes renders them highly susceptible to metabolic disturbances that lead to cellular degeneration and necrosis (Box 8-3). This section will consider the patterns of hepatic degeneration, responses of the liver to injury, and inflammation of the liver.

8.1.1.2.3

### Hepatobiliary Injury

8.1.1.2.3.1

### Necrosis and apoptosis

The epithelial cells of the liver, hepatocytes, and biliary epithelium are the principal targets of most liver diseases. Sublethal injury to hepatocytes is characterized by cell swelling (hydropic degeneration), steatosis, or atrophy. Cells that have sustained a sublethal injury often remove damaged organelles by forming autophagosomes. Material that cannot be digested further is retained as lipofuscin, which is why after sublethal injury this pigment can often be found in affected cells and associated phagocytes.

### 8.1.1.2.3.1.1

#### Box 8-3 Mechanisms of Liver Injury

- Metabolic bioactivation of chemicals via cytochrome P450 to reactive species
- Stimulation of autoimmunity
- Stimulation of apoptosis
- Disruption of calcium homeostasis leading to cell surface blebbing and lysis
- Canalicular injury
- Mitochondrial injury

Data from Lee W: *N Engl J Med* 349:474-485, 2003.

By convention, cell death has been divided into two distinct processes. These are necrosis, characterized by cytoplasmic swelling, destruction of organelles, and disruption of the plasma membrane, and apoptosis or programmed cell death, characterized by one of several active processes involving caspases that lead to cell shrinkage and an intact cell membrane. Necrosis is triggered by lethal injury. Necrotic cells typically exhibit karyorrhexis and fragmentation of the cell body. Coagulative necrosis results from sudden denaturation of hepatocytes and produces swollen hepatocytes with a preserved eosinophilic cytoplasmic outline and karyorrhexis or karyolysis. Lytic necrosis is characterized by a loss of hepatocytes and an influx of erythrocytes into the vacant space or condensation of the reticular connective tissue (collagen and other extracellular matrix) scaffolding of the liver that once supported the hepatocytes.

Classical apoptosis is triggered by an interaction between tumor necrosis factor- $\alpha$  or Fas ligand and specific receptors on the cell membrane leading to caspase activation, although other pathways, including those involving mitochondrial cytochrome-c, have been identified. Apoptosis is recognized by the formation of acidophilic bodies, which are brightly eosinophilic, homogeneous, round structures that can be found between hepatocytes, within the lumen of sinusoids, or within macrophages or hepatocytes. A detailed review of cell death is beyond the scope of this section but is covered in [Chapter 1](#). However, recent evidence reveals that there may some overlap between necrosis and apoptosis, depending on the cell type and the type and dose of injurious agent. Thus both hepatic necrosis and apoptosis can be produced by the same agent and can occur in the same liver.

402

403

### 8.1.1.2.3.2

#### Patterns of hepatocellular degeneration and necrosis

Although the liver is subjected to a wide variety of different insults, the cellular degeneration and/or necrosis that results invariably occurs in one of three morphologic patterns:

- Random hepatocellular degeneration and/or necrosis
- Zonal hepatocellular degeneration and/or necrosis
- Massive hepatocellular degeneration and/or necrosis

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.2.3.2.1

### Random hepatocellular degeneration.

Random hepatocellular degeneration and/or necrosis is characterized by the presence either of single cell necrosis throughout the liver or multifocal areas of necrotic hepatocytes. These areas are scattered randomly throughout the liver; there is no predictable location within a lobule. This pattern is typical of many infectious agents, including viruses, bacteria, and certain protozoa. Lesions may be obvious grossly as discrete, pale or less often dark red foci that are sharply delineated from the adjacent parenchyma (Fig. 8-10, A). The size of such foci is variable, ranging from tiny (<1 mm) to several millimeters. Hepatocytes in affected areas are either degenerated or necrotic because of the injurious effects of the infectious agents and the stage of the process (Fig. 8-10, B).

8.1.1.2.3.2.2

### Zonal hepatocellular degeneration and/or necrosis.

Zonal hepatocellular degeneration and/or necrosis or, as it is more simply termed, zonal change, affects hepatocytes within defined areas of the hepatic lobule. The zones are centrilobular (periacinar), midzonal (between centrilobular and periportal areas), or periportal (centroacinar) areas. Extensive zonal change within the liver, regardless of location within the lobule, typically produces a liver that is pale and modestly enlarged with rounded margins, has increased friability, and characteristically has an enhanced lobular pattern on the capsular and cut surface of the organ (Fig. 8-11). Degenerated hepatocytes swell and, when the majority of hepatocytes in a zone are affected, that portion of the lobule appears pale. In contrast, once the hepatocytes in a particular zone of the lobule have become necrotic, this results in dilation and congestion of sinusoids so that the affected zone appears red. Although zonal change typically produces an enhanced lobular pattern, microscopic examination is usually required to determine the type of zonal change. Specific forms of zonal change are described next.

8.1.1.2.3.2.2.1

### Centrilobular degeneration and necrosis.

Centrilobular degeneration and necrosis of hepatocytes is particularly common (Fig. 8-12), as this portion of the lobule receives the least oxygenated blood and is therefore susceptible to hypoxia, and it has the greatest enzymatic activity (mixed-function oxidases) capable of activating compounds into toxic forms. Centrilobular necrosis can result from a precipitous and severe anemia or right side heart failure. Similarly, passive congestion of the liver results in hypoxia as a result of stasis of blood and produces atrophy of centrilobular hepatocytes.

Fig. 8-10 **Random hepatocellular injury, liver.** **A**, Equine herpes virus infection, foal. Random foci of viral-induced lytic necrosis. **B**, Salmonellosis, focal necrosis and inflammation, pig. The random pattern of hepatocellular necrosis and inflammation caused by septicemic *Salmonella* spp. can also be seen within the hepatic lobules. H&E stain. (**A**, Courtesy Drs. J. King and L. Roth, College of Veterinary Medicine, Cornell University. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.1.1.2.3.2.2.2

Paracentral (periacinar) cellular degeneration.

Paracentral (periacinar) cellular degeneration involves only a wedge around the central vein because only the periphery of one acinus is affected, typically reflecting the action of a direct-acting toxin that requires bioactivation (Fig. 8-13) or severe, acute anemia. As several acini border on a single central vein (terminal hepatic venule), changes induced by hypoxia may not be present equally in all acini, and thus hepatocytes at the periphery of one acinus can have more severe change than those in adjacent acini.

403

404

**Fig. 8-11 Zonal hepatocellular injury, liver, horse.** Accentuation of the normal lobular pattern is evident on the capsular surface of the liver. This is not a specific change, as it may be associated with zonal hepatocellular degeneration and/or necrosis (regardless of lobular location), passive congestion, or diffuse cellular infiltration of the portal and periportal areas (often reflecting hepatic involvement of hematopoietic neoplasms, such as lymphoma and myeloproliferative disorders). (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

Fig. 8-12 **Centrilobular necrosis, zonal hepatocellular injury, liver, pig.** Centrilobular necrosis (periportal or zone 3) is characterized by a circumferential zone of hepatocellular necrosis surrounding the terminal hepatic venule (central vein [C]). H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 8-13 Paracentral degeneration and necrosis, zonal hepatocellular injury, liver, cow.** Rather than a pattern of complete circumferential necrosis, a wedge-shaped area of hepatocytes is damaged. In this case, the paracentral lesion consists of necrotic hepatocytes to the left and other hepatocytes with hydropic degeneration. This wedge is the apex of the diamond-shaped liver acinus (zone 3) and reflects the partitioning of the lobule based on the inflow of blood from each of the individual portal tracts that surround the lobule. This change can be seen as an early manifestation of hepatic hypoxia in animals with anemia or right-sided heart failure and precedes centrilobular necrosis. C, Central vein. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

8.1.1.2.3.2.2.3

### Midzonal degeneration and necrosis.

Midzonal degeneration and necrosis are unusual lesions in domestic animals but have been reported in pigs and horses with aflatoxicosis and cats exposed to hexachlorophene ([Fig. 8-14](#)).

8.1.1.2.3.2.2.4

### Periportal degeneration and necrosis.

Periportal degeneration and necrosis are also uncommon but may occur following exposure to toxins, such as phosphorus, that do not require metabolism by mixed function oxidases (most active in the centrilobular hepatocytes) to cause injury ([Fig. 8-15](#)). Some of these compounds may be metabolized to injurious intermediates by cytoplasmic enzymes found in periportal

404

405

## Pathologic Basis of Veterinary Disease, 4th Edition

hepatocytes. Alternatively, some of these toxins may not require metabolism and produce hepatocyte injury in the first hepatocytes that they encounter as they flow from the portal areas.

**Fig. 8-14 Midzonal necrosis, zonal hepatocellular injury, liver, horse.** Midzonal necrosis is the least common pattern of hepatic injury. Hepatocytes in the middle portion of the lobule (zone 2) are affected and hepatocytes in the other regions are spared. *C*, Central vein; *P*, portal vein. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

**Fig. 8-15 Periportal necrosis, zonal hepatocellular injury, liver, horse.** Periportal (periacinar or zone 1) necrosis is an uncommon pattern of hepatocellular injury. Hepatocytes surrounding the portal tracts (*P*) are affected. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.2.3.2.2.5

### Bridging necrosis.

Bridging necrosis is the result of confluence of areas of necrosis. Bridging may link centrilobular areas (central bridging) or centrilobular areas to periportal areas (Fig. 8-16).

**Fig. 8-16 Bridging necrosis, zonal hepatocellular injury, liver.**

*Bridging necrosis* refers to a pattern characterized by connection of areas of necrosis between different lobules. Three patterns of bridging necrosis are recognized: central to central, as seen here; portal to portal; and central to portal. *P*, Portal area. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 8-17 **Massive necrosis, liver.** **A**, Pig, cut surface. *Massive necrosis* refers to a pattern of necrosis that involves an entire hepatic lobule, as seen here. **B**, Dog. The entire population of hepatocytes within the lobule has undergone necrosis. *P*, Portal area. H&E stain. (**A**, Courtesy Dr. D. Cho, College of Veterinary Medicine, Louisiana State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.1.1.2.3.2.3

### Massive necrosis.

Massive necrosis is not necessarily, as the name might be taken to imply, necrosis of the entire liver, but rather the term describes necrosis of an entire hepatic lobule or contiguous lobules (Fig. 8-17, A). All hepatocytes within affected lobules are necrotic. The gross appearance of the liver varies with the maturity of the lesion. If, in acute cases, the majority of the parenchyma is affected, the liver may initially be modestly increased in size with a smooth external surface and dark parenchyma because of extensive congestion. At first, necrotic hepatocytes lyse and the residual stroma becomes condensed. Regeneration does not occur because virtually all hepatocytes in the lobule are affected. Microscopically, affected areas consist of blood-filled spaces within a connective tissue stroma devoid of hepatocytes (Fig. 8-17, B). Later in the course of the process, stellate cells or other extracellular matrix-producing cells from the portal and centrilobular areas that may survive or migrate to the site of injury contribute new collagen (collagen I, in particular). The final result is collapse of the lobule and replacement of the lost hepatic parenchyma with a scar consisting of condensed stroma, including variable amounts and types of collagen. Grossly the liver may be smaller than normal with a wrinkled capsule. Partial involvement of the liver is characterized by depressed areas of parenchymal necrosis and vascular congestion scattered throughout the organ.

405

406

8.1.1.3

### MORPHOLOGIC CLASSIFICATION OF HEPATOBILIARY DISEASE

The nature and distribution of inflammatory lesions in the liver are usually dictated by the route of entry, the host inflammatory response, the nature of the infectious agent (e.g., virus, bacterium, fungus), and any predilection they have for involvement with a particular cell type in the liver. The hematogenous route of infection tends to cause a random multifocal distribution of lesions. Infections, usually bacterial, that ascend the biliary tract are typically centered in the bile ducts. Severe infections may affect the entire portal tract and extend into the adjacent parenchyma. Penetrating wounds cause discrete areas of inflammation with or without necrosis that are evident on the capsule and extend into the hepatic parenchyma. Liver injury should be characterized by: the pattern of involvement (multifocal random, zonal, or massive), type of inflammatory cells involved (neutrophils, lymphocytes, plasma cells, eosinophils, or macrophages), evidence of necrosis or fibrosis, severity of these processes, evidence of regeneration, and the presence of an etiologic agent or agents. The type of inflammatory response and the duration of the injury can help identify the infectious agents.

8.1.1.3.1

### Acute Hepatitis

Inflammation of the liver parenchyma is termed hepatitis. Acute hepatitis is characterized by inflammation, hepatocellular necrosis, and apoptosis. The proportion and type of inflammatory cells involved varies considerably depending on the cause of inflammation, the host response, and the stage or age of the lesion. Characterization of the type of inflammation usually requires microscopic evaluation. In many forms of acute hepatitis, particularly bacterial and protozoal infections, neutrophils accumulate in response to the usual chemotactic stimuli. Random foci of neutrophilic hepatitis, as a consequence of embolic localization of bacteria, are relatively common in all species. In neonates—especially calves, lambs, and foals—bacteria, such as *Escherichia coli*, usually seed the liver via the umbilical veins or less often the portal venous or hepatic arterial systems. Acute hepatitis produced by viral infections, such as herpesvirus infection in many species, is more frequently characterized by a random distribution of necrosis and apoptosis with minimal inflammation or infiltrations of lymphocytes.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.3.2

### Chronic Hepatitis

Chronic hepatitis results when there is continued inflammation as a result of persistence of an antigenic stimulus. In the absence of such a stimulus, inflammation rapidly resolves. Chronic hepatitis is characterized by fibrosis; accumulation of mononuclear inflammatory cells, including lymphocytes, macrophages, and plasma cells; and, frequently, regeneration. Neutrophils often are present in chronic unresolved hepatic inflammation such as that which characterizes some forms of canine chronic hepatitis. The proportion and distribution of each of these elements varies with the inciting cause and host response. Local variation within the liver can also occur.

Different terms are used to distinguish separate types of chronic hepatitis. Granulomatous hepatitis may be obvious grossly if it produces discrete granulomas of sufficient size. These may be focal or diffuse. Chronic suppurative hepatitis is usually manifested as discrete or multiple abscesses. Focal lesions, such as abscesses or granulomas, often are sufficiently localized so that they do not alter hepatic function. In contrast, diffuse and severe chronic hepatitis, as seen in dogs, usually leads to loss of hepatic parenchyma and architectural distortion of the liver as a consequence of fibrosis and nodular parenchymal regeneration. This process can proceed to end-stage hepatic disease with hepatic failure and its associated constellation of clinical signs. The form of chronic hepatitis that has been referred to as chronic active hepatitis is discussed in a separate section next.

8.1.1.3.3

### Nonspecific Reactive Hepatitis

Nonspecific reactive hepatitis is a diffuse process distributed throughout the liver in response to some systemic illness, most often the gastrointestinal tract, or is the residuum of prior liver inflammation. Typically, there is a mild inflammatory infiltrate in the portal tract and possibly the parenchyma without evidence of necrosis. In acute cases, there is a minimal to mild infiltrate of neutrophils within the connective tissue of the portal tracts that may vary in intensity. Mononuclear cells, primarily lymphocytes and plasma cells, predominate in more chronic manifestations. Pigmented macrophages containing hemosiderin, lipofuscin, or both may be scattered throughout the parenchyma. Mononuclear inflammatory cells may also be evident within the hepatic parenchyma and at the periphery of central veins. Kupffer cells are usually reactive (i.e., they appear somewhat swollen because of abundant cytoplasm and display prominent nuclei as well).

406

8.1.1.3.4

### Cholangitis

Cholangitis is characterized by inflammation that is centered on the biliary tract. The inflammatory cell population and the degree of fibrosis will vary with the type and duration of injury. Cholecystitis refers to inflammation of the gallbladder.

407

8.1.1.3.5

### Cholangiohepatitis

Inflammation that affects the biliary ducts and hepatic parenchyma is termed cholangiohepatitis. In most cases of intrahepatic disease, the primary focus of inflammation can be identified as affecting either the hepatocytes or the biliary tree, but on occasion both components of the liver are affected, usually as an extension of biliary disease to involve the periportal hepatocytes, and in that circumstance the term *cholangiohepatitis* should be used.

## Pathologic Basis of Veterinary Disease, 4th Edition

8.1.1.4

### DISTURBANCES OF BILE FLOW AND ICTERUS

Hepatic injury is frequently manifested as an increased concentration of conjugated or unconjugated bilirubin in blood called hyperbilirubinemia. High concentrations of bilirubin (> approximately 2 mg/dl) can produce jaundice (icterus), a yellow discoloration of tissue that is especially evident in tissue rich in elastin, such as the aorta and sclera (Fig. 8-18). This concentration is within the reference range for horses, so horses may not be hyperemic at this level because their reference range reaches that concentration. However, in other species, hyperbilirubinemia can occur once the concentration exceeds 0.5 mg/dl (dog) and therefore the patient is hyperbilirubinemic, but icterus will not be detected until it exceeds 2 mg/dl. Maximal accumulation of bilirubin in tissues takes about 2 days and explains why some animals with acute hepatic failure may have only slight icterus.

**Fig. 8-18 Icterus, dog.** Icterus and jaundice are terms that refer to the yellow discoloration of tissue, by bilirubin, in this case evident in the fat and serosa. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

The causes of hyperbilirubinemia include the following:

1. Overproduction of bilirubin as a consequence of hemolysis, particularly severe intravascular hemolysis, which overwhelms the liver's capacity to remove bilirubin from the plasma and to secrete conjugated bilirubin into bile. The destruction of damaged red blood cells by extravascular hemolysis can also increase the burden of bilirubin presented to the liver. Hypoxia secondary to anemia may also play a role. Secretion of conjugated bilirubin into bile canaliculi is an energy-dependent process and is the rate-limiting step in bilirubin excretion in most species.
2. Decreased uptake, conjugation, or secretion of bilirubin by hepatocytes arising as a consequence of severe, diffuse hepatic disease, whether acute or chronic.

## Pathologic Basis of Veterinary Disease, 4th Edition

3. Reduced outflow of bile (cholestasis). Cholestasis is defined as a defect in bile secretory mechanisms that leads to an accumulation in the blood of substances normally excreted into the bile. Cholestasis occurs as a consequence of either obstruction of the biliary ducts (extrahepatic cholestasis) or impairment of bile flow within canaliculi (intrahepatic cholestasis).

Obviously, hepatic dysfunction is not the only cause of hyperbilirubinemia and icterus. In fact, icterus in ruminants is usually a consequence of severe intravascular hemolysis and less often a sequel to hepatic damage. Horses often manifest icterus with acute hepatic dysfunction, but icterus may or may not occur in horses with chronic hepatic disease. Interestingly, “physiologic icterus” is also common in the horse, and horses deprived of feed for several days can become icteric because uptake of bilirubin from the plasma by hepatocytes is decreased. Icterus in carnivores occurs as a consequence of either hemolysis or hepatic dysfunction. Inherited metabolic abnormalities can also lead to abnormal concentrations of serum bilirubin. In Southdown sheep with certain mutations, bile is ineffectively taken up from the circulation and a persistent unconjugated bilirubinemia develops, although icterus is rarely apparent because there is sufficient excretion despite the mutation. Corriedale sheep may have a mutation that leads to deficient conjugated bilirubin excretion. Affected sheep have persistently elevated plasma bilirubin concentration, but jaundice is not apparent. Other compounds that are normally excreted through conjugation also accumulate in the liver of affected sheep. The livers are dark and discolored due to accumulated polymerized catecholamine metabolites that accumulate in lysosomes. These residues resemble lipofuscin histologically.

Cholestasis can be divided into two types: intrahepatic and extrahepatic. Intrahepatic cholestasis can result from (1) wide spectrum of liver injury affecting the ability of hepatocytes to metabolize and excrete bile, (2) hemolysis, which produces an abundance of bilirubin for excretion and diminishes the supply of oxygen for hepatocyte metabolism, or (3) inherited abnormalities of bile synthesis that inhibit the excretion of bile. Extrahepatic obstruction is produced by obstruction of the extrahepatic bile ducts. This can occur by intraluminal obstruction (calculi or possibly parasites) or extraluminal means, including neoplasia or adjacent inflammation, often involving the pancreas. Cholestasis, if sufficiently severe, can produce a greenish brown discoloration to the liver (Fig. 8-19, A).

407

408

**Fig. 8-19 Hepatic bilirubin retention, icterus, liver. A, Cat.** The liver is markedly yellowed by retained bilirubin. **B, Canalicular bilirubin, acute hemolytic anemia, calf.** Acute hemolysis caused by babesiosis has led to a dramatic increase in bilirubin production and distention of canaliculi, clearly demonstrating the location of canaliculi between hepatocytes. **Fig. 8-20 Chronic extrahepatic cholestasis, cholelithiasis, liver, horse.**

There is reduplication of bile ducts (*arrows*) and extensive fibrosis (*F*) throughout the portal tract (biliary fibrosis) as a consequence of prolonged stasis and subsequent leakage of bile. H&E stain.

(Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Histologically, acute intrahepatic cholestasis is characterized by formation of bile plugs within canaliculi (Fig. 8-19, *B*). As intrahepatic cholestasis becomes more chronic, bile that has been released from hepatocytes is taken up by Kupffer cells and can be detected within their cytoplasm.

Acute extrahepatic obstruction is characterized by edema of the portal areas, a mild neutrophilic inflammatory cell infiltrate, and a proliferative reaction by the biliary epithelium of the bile ducts. In chronic extrahepatic biliary obstruction, portal areas are enlarged by deposition of fibrosis, and there is a prominent laminar, circumferential fibrosis of bile ducts (Fig. 8-20). Biliary hyperplasia characterized by proliferation of small-caliber bile ducts is often prominent. Pigmented macrophages, containing bile, and mixed inflammatory infiltrates are also present. In severe cases, bridging fibrosis connecting portal tracts may develop.

Complete biliary obstruction leads to maldigestion of fats and a characteristic clay-colored stool termed acholic feces because of the lack of normal dark pigment, stercobilin, the bilirubin-derived pigment produced by bacterial metabolism (Fig. 8-21).

### 8.1.1.5

#### RESPONSE OF THE LIVER TO INJURY

Following destruction of hepatic parenchyma, regeneration of parenchyma, replacement by fibrosis, and biliary hyperplasia may occur. The outcome of a given hepatic insult depends on the nature and duration of the insult, and survival of the host.

## Pathologic Basis of Veterinary Disease, 4th Edition

8.1.1.5.1

### Regeneration

A characteristic feature of the liver is the ability to rapidly and efficiently regenerate lost hepatic mass. 408

Experimentally, as much as two thirds of the liver can be excised from a healthy animal without signs of hepatic dysfunction, and the liver is rapidly regenerated. In addition to replication of hepatocytes, there is a wave of replication in bile duct epithelium, endothelium, and sinusoidal lining cells that is coordinated with hepatocyte replication. 409

**Fig. 8-21 Intrahepatic biliary obstruction, intestine, dog.** In cases of complete biliary obstruction, bile is unable to reach the intestine and as a result stool(s) lacks the characteristic dark color produced by bile pigments. (Courtesy College of Veterinary Medicine, North Carolina State University.)

Regeneration usually takes place by replication of mature hepatocytes. In most circumstances, this leads to an increase in the size of existing lobules; however, recent data suggest that some new lobule formation can also occur through subdivision of existing lobules. Following removal of liver lobes only, the remaining liver lobes persist, and no new lobe formation occurs.

Individual cell necrosis leads to local proliferation by regeneration of adjacent hepatocytes. Scattered foci of necrotic hepatocytes are quickly replaced through cell division of adjacent hepatocytes. Necrosis in the centrilobular area of the lobule leads to a wave of hepatocyte proliferation in the hepatocytes in the remaining areas of the lobule, particularly the periportal hepatocytes. In some circumstances, such as necrosis of nearly all hepatocytes or exposure to certain chemical toxins that inhibit replication of mature hepatocytes, replacement of hepatocytes lost by necrosis occurs through proliferation of hepatocyte stem cells or oval cells. This process is most often observed in experimental manipulations of laboratory rodents, but probably occurs in naturally occurring cases of hepatotoxicity also. These cells reside in the connective tissue of the portal tracts and have the ability to differentiate into hepatocyte or bile duct epithelium. Histologically, they are identified as small basophilic cells with an oval shape. They are not apparent in most circumstances of hepatic regeneration, but can be abundant in experimental studies of hepatic regeneration.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The body carefully orchestrates hepatic regeneration to replace lost hepatocyte mass along with bile ducts and vessels without producing excess liver. A variety of growth factors, including transforming growth factor- $\alpha$  and hepatocyte growth factor, stimulate hepatocyte replication. Once normal hepatic mass has been established, macrophages release transforming growth factor- $\beta$ , which in concert with other less well characterized factors stops hepatic parenchymal cell proliferation.

Extensive hepatic necrosis is usually followed by parenchymal regeneration without scarring as long as the normal extracellular matrix (reticulin) scaffolding of the affected portion remains intact and has not collapsed, as in massive hepatic necrosis. However, repetitive injury or massive necrosis can disrupt the normal lobular architecture, and there may be parenchymal collapse after removal of the dead hepatocytes and/or stromal collapse with repair by collagen synthesis (postnecrotic scarring) (Fig 8-22). Even when necrosis of hepatocytes is continuous, the liver will attempt to regenerate its functional mass. However, prolonged regenerative effort with damage to the normal extracellular matrix scaffolding of the liver often results in nodular proliferations of parenchyma, which architecturally distort the liver. Although regenerative nodules may reconstitute a proportionately large amount of hepatic mass, adequate function is rarely attained. Blood flow into the regenerative nodules and bile flow out of the nodules is abnormal and as a result, hepatic function cannot be reestablished. As the nodules develop, the portal tract vessels and the central veins develop communications within the fibrous septa between nodules, which leads to vascular shunts between the portal vein and the central vein that bypass hepatocytes within the nodules.

### 8.1.1.5.2

#### Fibrosis

Fibrosis is one of the more common manifestations of chronic liver injury. The pattern of fibrosis is frequently a useful indicator of the type of insult that produces the lesion. The significance of fibrosis depends on its effect on hepatic function and its reversibility. Despite the considerable regenerative capacity of the liver, hepatic fibrosis, when sufficiently severe, can be lethal.

In the normal liver, fibrillar collagens I and III are confined primarily to the connective tissue of the portal tracts and immediately around the terminal hepatic venule (central vein). Collagen IV is the most abundant collagen type in the reticulin framework of the sinusoids, but it is present in only small amounts. A delicate scaffolding of collagen and other extracellular matrix components, which are produced by stellate cells, endothelial cells and hepatocytes, make up the normal framework of the sinusoid. This stroma in the space of Disse supports the endothelial cells and maintains their relationship to the hepatocytes.

Hepatic fibrosis is an overall increase in the extracellular matrix within the liver. In a fibrotic liver, there is an increase in the amount of extracellular matrix and a change in the types of collagen and their site of deposition. A severely fibrotic liver can contain up to six times as much collagen and proteoglycan as a normal liver. Hepatic fibrosis is characterized by an increase of fibrillar collagens, type I and type III, and nonfibrillar collagen XVIII within the space of Disse, the portal areas, and the area surrounding the central veins. In addition to an increase in collagens, there is also a commensurate increase in the extracellular matrix components, proteoglycans, fibronectin, and hyaluronic acid.

409

410

**Fig. 8-22 Schematic diagram of the effects of hepatic injury on the development of fibrosis.** Acute hepatic centrilobular injury (2) that occurs only once usually resolves, and normal liver architecture returns (1, 3). Repeated bouts of injury or severe injury can initiate hepatic fibrosis (4). In the earliest stages, fibrosis may be reversible, but as fibrosis progresses it reaches a point at which repair is not likely. Fibrosis starts as fine branches of collagen deposition between portal areas or central areas or dissecting into the hepatic parenchyma (5, 6). Over time, greater amounts of collagen and other extracellular matrix are deposited and the lobular architecture becomes progressively distorted. In the end-stage liver, nodular regeneration (7, 8) and extensive, circumferential fibrosis are typical. The regenerative nodules shown here (7, 8) are at an early stage of regeneration. As shown [Fig. 8-24](#), they will regenerate to form nodules that will commonly exceed the size of normal hepatic lobules. These nodules will often compress (7) the central vein(s) of hepatic lobules within and adjacent to those from which they arose.

The stellate cells (Ito cells and lipocytes) have a central role in hepatic fibrosis, although it should be noted that there are myofibroblastic cells with similar capabilities found within the connective tissue of the portal areas and connective tissue surrounding the central vein. In the normal liver, stellate cells occupy the space of Disse (a subendothelial position in the sinusoid) nestled between hepatocytes. They are characterized by the presence of large lipid-containing vacuoles in their cytoplasm (Fig. 8-8). The vacuoles are a primary storage site for retinyl esters, including vitamin A. Stellate cells are positioned in the space of Disse around the circumference of the endothelium of the sinusoids and have been likened to pericytes in other organs, such as the mesangial cells of the renal glomerulus. Hepatic stellate cells have been shown to have a role in the control of the diameter of the sinusoids and consequently the flow of blood through the sinusoids.

When the liver is injured, these cells go through a progressive phenotypic change from the typical lipid-storing cell to a cell with a myofibroblastic appearance (Fig. 8-23). When they are activated, they express smooth muscle actin and desmin, a marker usually found in muscle cells. Once these cells have switched phenotype to the myofibroblast phenotype, they begin synthesis of collagen types I, III, and IV. They also produce other extracellular matrix components, including laminin and chondroitin sulfate proteoglycans. Hepatocytes synthesize few or no matrix proteins, and the large sum of matrix proteins is derived from the hepatic stellate cells. The type of hepatic injury does not seem to be important in the genesis of hepatic fibrosis. Chemical injury, biliary obstruction, and iron overload produce similar patterns of activation of hepatic stellate cells.

The site in which collagen is deposited in the liver has a significant impact on liver function. Perisinusoidal fibrosis can have a severe effect on hepatic function. In addition to collagen and extracellular matrix deposits, there is a loss of gaps in the endothelial cells and a loss of microvilli on the luminal surface of the hepatocytes. These changes have been termed capillarization of the sinusoids because the alterations in the sinusoids result in a vascular structure that more closely resembles a capillary than a sinusoid. The functional effect of this microanatomic change is profound. The ability of the liver to carry out its synthetic, catabolic, and excretory roles is severely compromised by the reduced exposure of hepatocytes to plasma.

Within the hepatic lobule, the site of fibrosis can be indicative of the type of insult. Most often, chronic toxic injury produces centrilobular (periportal) fibrosis. This region is affected because the centrilobular hepatocytes are the site of metabolism for most drugs. Long-standing right side heart failure can cause fibrosis in this site as well. Periportal (centroacinar) fibrosis can result from chronic inflammatory conditions or a small group of toxins that affect the periportal hepatocytes because they do not require metabolism by the cytochrome p450 enzymes to produce an injurious metabolite. Fibrosis may be limited to individual lobules, but in more severe injuries the areas of fibrosis can be more extensive. Bridging fibrosis, which is analogous to bridging necrosis, implies fibrosis that extends from one portal tract to another or from portal tracts to central veins. Bridging fibrosis is more likely to impair hepatic function than focal forms of hepatic fibrosis; however, all forms of hepatic fibrosis, if sufficiently severe, lead to impaired hepatic function. However, because of the enormous reserve capacity of the liver, fibrosis is usually quite extensive before there are clinical signs of hepatic dysfunction.

**Fig. 8-23 Schematic diagram of a fibrotic hepatic sinusoid.** Contact between the plasma and the hepatocytes is dramatically reduced. The sinusoidal endothelial cells have lost their gaps. The space of Disse contains abundant collagen type I fibers that have been synthesized by activated hepatic stellate cells. The hepatic stellate cells have eliminated the lipid vacuoles and assumed a myofibroblastic morphology with cell extensions that often surround the endothelial cells (not shown here). Hepatocyte microvilli have been lost on the apoptotic hepatocyte, and this loss begins with the onset of hepatocyte dysfunction and degeneration. *ET-1*, Endothelin-1; *MCP-1*, macrophage chemotactic protein-1; *PDGF*, platelet-derived growth factor; *TGF- $\beta$* , transforming growth factor- $\beta$ ; *TNF*, tumor necrosis factor. (Schematic based on concepts presented in Friedman SL: J Biol Chem 275:2247-2250, 2000; and Crawford JM: Curr Op Gastroenterol 13:175-185, 1997.)

A single event of widespread hepatocellular necrosis is sometimes followed, not by the usual regenerative response, but by fibrosis and condensation of the preexisting connective tissue stroma that results in formation of bands of dense connective tissue. This process is referred to as postnecrotic scarring.

411

412

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Other patterns of hepatic fibrosis can occur, including biliary fibrosis (centered on bile ducts in the portal triads), focal or multifocal hepatic fibrosis (randomly scattered throughout the hepatic parenchyma)—which is produced, for example, by migrating nematode larvae—and diffuse hepatic fibrosis (affects all regions of the lobule and is present throughout the liver). Diffuse fibrosis with hyperplastic nodule formation is by definition cirrhosis. Different hepatic insults may produce different patterns of fibrosis, but when fibrosis is severe (end-stage liver disease), it frequently is impossible to determine either the cause or the initial pattern of fibrosis.

8.1.1.5.3

### Biliary Hyperplasia

Biliary hyperplasia, which is proliferation of new biliary ducts within the portal areas and periportal regions, can be a relatively nonspecific response to a variety of insults to the liver. The mechanism responsible for this proliferation is unknown. Biliary hyperplasia can occur swiftly, particularly in young animals, but is usually regarded as a lesion seen in long-standing hepatic injury. Biliary hyperplasia occurs particularly after diseases that obstruct normal bile drainage.

8.1.1.5.4

### End-stage Liver or Cirrhosis

The best accepted definition for cirrhosis was pronounced by the World Health Organization in 1977 and is as follows: “a diffuse process characterized by fibrosis and the conversion of the normal liver architecture into structurally abnormal lobules (Fig. 8-24).” As it is the final, irreversible result of any one of several different hepatic diseases, the term *end-stage liver* is appropriate, particularly because the term *cirrhosis* is neither descriptive nor precise in meaning and originally meant “tawny yellow.” Another authority states that the hallmark is the total absence of any normal lobular architecture. The architecture of the liver is altered by loss of hepatic parenchyma, condensation of reticulin framework, and formation of tracts of fibrous connective tissue. Regeneration of hepatic tissue between fibrous bands leads to the formation of variably sized regenerative nodules (Fig. 8-25). The entire liver is thus distorted and consists of nodules of regenerating parenchyma separated by fibrous bands, which appear as depressions on the surface (Fig. 8-24).

Lobular dissecting hepatitis is a form of cirrhosis usually seen in young dogs. The condition is frequently fatal and has no known cause. Affected livers tend to be smooth and small, rather than the multinodular livers seen in typical cirrhosis. Histologically the livers are characterized by fine septa with increased fibrosis that dissect the hepatic plates, distort the lobular architecture, and isolate small aggregates or individual hepatocytes (Fig. 8-26). Inflammation in the tissue is usually mild to moderate, and the inflamed area contains mononuclear cell infiltrates.

**Fig. 8-24 End-stage liver (cirrhosis), dog.** End-stage liver from a dog that had received phenobarbital for many years. The liver is small, firm, and irregular with nodules of regenerative parenchyma separated by tracts of fibrous connective tissue. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Profound vascular abnormalities with serious consequences for the health of affected patients occur in this condition, including multiple abnormal vascular anastomoses between the portal vein and the systemic vasculature, as a consequence of the increased portal pressure. Also, venous shunts between the central veins and the portal veins, and arteriovenous shunts between the hepatic arteries and the central veins, can occur within the regenerative nodules.

The potential causes of an end-stage (cirrhotic) liver are numerous (Box 8-4). Chronic toxic insult results from the continued ingestion of any hepatotoxin (e.g., herbivores ingesting toxic plants, such as those that contain pyrrolizidine alkaloids, and the long-term administration of anticonvulsant drugs, such as primidone for dogs). Chronic extrahepatic biliary obstruction and cholestasis leads to extensive fibrosis, which primarily affects the portal triads, but the fibrosis can eventually extend into the adjacent hepatic parenchyma. Chronic inflammation of the liver (hepatitis) or biliary tract (cholangitis) may lead to an end-stage liver. Although infection of the liver typically is focal or multifocal, diffuse hepatitis and subsequent fibrosis occurs in disease entities such as so-called canine chronic (chronic-active) hepatitis. Chronic passive hepatic congestion eventually leads to fibrosis near central veins, which is sometimes termed cardiac sclerosis and which can progress to cardiac cirrhosis. The actual amount of fibrosis is usually small. Abnormal storage or metabolism of metals, such as copper, as occurs in Dalmatians and Bedlington and West Highland white terriers with hereditary copper accumulations, may produce an end-stage liver. A variety of more poorly defined disease entities can lead to progressive hepatocellular injury and hepatic fibrosis resulting in end-stage hepatic disease.

412

413

**Fig. 8-25 End-stage, liver, dog.** **A**, Histologic appearance of end-stage liver disease. **Fig. 8-26 Lobular dissecting hepatitis, liver, dog.** Lobular dissecting hepatitis is a form of end-stage liver characterized microscopically by fine septa of extracellular matrix (chiefly collagen) that divide hepatocyte plates into small clusters of individual hepatocytes. Because of the disruption of blood flow through the liver and the failure of hepatocytes to come in contact with blood, there is profound hepatic dysfunction. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

The end-stage liver obviously cannot perform its normal functions, so the clinical manifestations of hepatic failure invariably occur in affected animals. However, the cause of the hepatic damage that leads to the end-stage liver frequently cannot be determined at the time signs of hepatic failure are observed.

### 8.1.1.5.5

#### Hepatic Failure

The liver has considerable functional reserve and regenerative capacity. In healthy animals, more than two thirds of the hepatic parenchyma can be removed without significant impairment of hepatic function and normal hepatic mass can be regenerated in a matter of days. This process of tissue removal can be repeated several times, particularly in younger animals, and function is retained. In all species, clinical signs from hepatic derangement are similar, regardless of their cause. These are manifest, however, only when the liver's considerable reserve and regenerative capacity are depleted or when biliary outflow is obstructed. Only lesions that affect the majority of the hepatic parenchyma are likely to produce the signs of hepatic failure because focal lesions rarely destroy sufficient parenchyma to deplete the liver's reserve. The term *hepatic failure* implies loss of adequate hepatic function as a consequence of either acute or chronic hepatic damage; however, all hepatic functions are not usually lost at the same time. The potential consequences of hepatic dysfunction and failure include: (1) hepatic encephalopathy; (2) disturbances of bile flow with a resultant hyperbilirubinemia; (3) a variety of metabolic disturbances; (4) vascular and hemodynamic alterations, such as shunting of portal blood into the systemic circulation bypassing the

8.1.1.5.5.2

### Hepatic encephalopathy

Hepatic failure can result in a metabolic disorder of the central nervous system termed hepatic encephalopathy (synonyms: hepatic coma or portosystemic encephalopathy). Neurologic manifestations range from depression and other behavioral changes to mania and convulsions. Affected horses may walk aimlessly. The central feature of this disorder is abnormal neurotransmission in the central nervous system and the neuromuscular system. Undetermined as yet are the specific metabolites that cause the neurologic dysfunction, but increased concentrations of plasma ammonia derived from amines absorbed from the gastrointestinal tract may be responsible. Normally, amines are absorbed from the intestines into the portal blood and metabolized by the liver. If they bypass the liver and gain access to the systemic circulation, they can exert toxic effects on the brain. These toxic products can enter the systemic circulation by two mechanisms. Blood can be shunted to the systemic circulation before it reaches the liver as a result of congenital portosystemic shunts or secondary to portal vein hypertension. Shunting of more than 10% to 15% of portal flow away from the liver is considered abnormal. Alternatively the toxic products may not be fully eliminated by the liver if there is sufficient liver disease. However, abnormal ammonia concentrations are not the only possible cause of hepatic encephalopathy. An altered balance of inhibitory and excitatory amino acid neurotransmitters,  $\gamma$ -aminobutyric acid, and L-glutamate, respectively, and increased brain concentrations of endogenous benzodiazepines are other possible explanations. Hepatic encephalopathy is common in ruminants and horses with hepatic failure, dogs and cats with congenital portosystemic shunts, and animals with end-stage liver (hepatic fibrosis and nodular regeneration) that leads to shunting of blood within regenerative nodules.

8.1.1.5.5.3

### Metabolic disturbances of hepatic failure

Hepatic failure can be manifested by a variety of metabolic disturbances. The type and duration of the hepatic disorder may influence the nature of the metabolic perturbation.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.5.5.3.1

### Bleeding tendencies.

Bleeding tendencies (hemorrhagic diathesis) sometimes accompany hepatic failure. Impaired synthesis of clotting factors, reduced clearance of the products of the clotting process, and metabolic abnormalities affecting platelet function can affect normal clotting, individually or in combination. All clotting factors, with the possible exception of factor VIII, are synthesized in the liver. In acute liver failure, diminished synthesis of clotting factors with a short half-life, such as factors V, VII, IX, and X, impairs the ability of blood to coagulate. In chronic liver disease, factor II (prothrombin) deficiency also contributes to diminished coagulation of blood. Diminished clearance of fibrin degradation products (FDPs), activated coagulation factors, and plasminogen factors by the damaged liver also perturbs clotting. Metabolic disturbances resulting from liver failure can affect platelet function and lead to synthesis of abnormal fibrinogen, a condition termed dysfibrinogenemia. Obstruction of the biliary system prevents the release of bile into the intestinal tract. The resulting impaired fat absorption limits vitamin K uptake from the intestine, which leads to an inactivity of factors II, VII, IX, and X. Acute hepatic failure may also precipitate disseminated intravascular coagulation, which can itself cause hemorrhagic diathesis. Impaired removal of activated clotting factors by the damaged liver is one potential mechanism for this. Acute hepatic failure in the horse and perhaps other species is sometimes accompanied by severe intravascular hemolysis, the cause of which is unknown.

8.1.1.5.5.3.2

### Hypoalbuminemia.

Hypoalbuminemia, as a consequence of hepatic dysfunction, usually reflects severe and chronic liver disease rather than acute disease. This is because of the relatively long half-life of plasma albumin (which ranges from 8 days in the dog to 21 days in cattle), which masks, for a period of time, the diminished albumin synthesis of the diseased liver. Severe diffuse liver disease can obstruct portal vein inflow, leading to portal hypertension, which accelerates the formation of ascites in affected animals. Loss of albumin in ascetic fluid or into the intestinal tract accentuates the loss of intravascular albumin, and widespread edema can result.

8.1.1.5.5.4

### Vascular and hemodynamic alterations of hepatic failure

Chronic hepatic injury typically is accompanied by extensive diffuse fibrosis of the liver, which increases resistance to blood flow through the liver. This in turn elevates pressure within the portal vein (portal hypertension). With time, collateral vascular channels open to allow blood in the portal vein to bypass the abnormal liver (acquired portosystemic vascular anastomoses, which connect the portal vein and its tributaries to the systemic venous circulation). Shunting of portal vein blood directly to the central vein can also occur within the fibrous septa formed in the liver. In addition, the increased pressure within the hepatic vasculature causes transudation of fluid (modified transudate) into the peritoneal cavity to produce ascites in several species, except in most cases horses. Transudation of fluid into the peritoneal cavity can be enhanced by hypoalbuminemia because there is a decreased colloid osmotic pressure in plasma. Hypoalbuminemia and reduced plasma colloid osmotic pressure can arise as a consequence of accelerated albumin loss into the lumen of the intestines as a result of portal hypertension or because of reduced hepatic synthesis of albumin and other plasma proteins by the diseased liver. Ascites associated with hepatic fibrosis in chronic liver disease (end-stage liver) or other causes of portal hypertension, such as right side heart failure, occurs most commonly in the dog and cat, occasionally in sheep, and rarely in horses and cattle.

415

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.1.1.5.5.5

Cutaneous manifestations of hepatic failure

8.1.1.5.5.5.1

Hepatocutaneous syndrome (necrolytic migratory erythema, superficial necrolytic dermatitis).

Hepatocutaneous syndrome is a syndrome of chronic hepatic injury and skin disease. The central diagnostic elements include crusting, erosions, and ulceration of the epidermis of the muzzle, mucocutaneous areas of the face, footpads, and pressure points of the skin in some dogs with severe hepatic disease (Fig. 8-27). The mechanism of cutaneous injury is not understood, but affected animals have characteristic multinodular livers, often with little fibrosis between the nodules. It seems likely that this histologically distinctive skin disorder results from abnormal hepatic metabolism. Typically the cutaneous lesions are parakeratosis, edema of the superficial epithelium, and basal cell hyperplasia.

**Fig. 8-27 Cutaneous necrosis, hepatocutaneous syndrome, foot pads, dog.** In some cases of hepatic failure, there is a syndrome of associated cutaneous necrosis termed hepatocutaneous syndrome. Footpads as well as areas of haired skin can be affected. (Courtesy Dr. T. Olivry, College of Veterinary Medicine, North Carolina State University.)

**Fig. 8-28 Cutaneous necrosis, photosensitization, skin, cow.** When the liver of herbivores fails and can no longer remove the photodynamic pigment phyloerythrin from the portal blood, skin with little pigment or hair covering, exposed to ultraviolet light, initially becomes acutely inflamed and may be followed by necrosis, as seen on the face of this cow. (Courtesy Dr. H. Gelberg, College of Veterinary Medicine, Oregon State University.)

8.1.1.5.5.2

### Photosensitization.

Injury to the skin resulting from activation of photodynamic pigments by ultraviolet light in the sun's rays is called photosensitization. Cutaneous lesions display hair loss, erythema, and necrosis ([Fig. 8-28](#)). Lesions are typically limited to hairless skin and to lightly or nonpigmented areas of skin. The sources of photodynamic pigments that can induce photosensitization include plants, certain drugs, and products of inherited disorders of porphyrin metabolism. The mechanism of tissue injury is not well characterized but is presumed to involve oxidative injury when photodynamic pigments that have been activated by the radiant energy of ultraviolet light subsequently release their energy to adjacent tissue. Hepatic dysfunction is only responsible for one form of photosensitization termed secondary (hepatogenous) photosensitization.

415

8.1.1.5.5.2.1

### Primary photosensitization.

Primary photosensitization occurs after a primary (preformed) photodynamic agent is ingested, absorbed into the blood, and deposited in tissue. Certain plants, such as St. John's wort (*Hypericum perforatum*) and buckwheat (*Fagopyrum esculentum*), and pharmaceutical agents, such as tetracycline or phenothiazine, contain compounds that are photodynamic.

8.1.1.5.5.2.2

### Secondary photosensitization.

Secondary or hepatogenous photosensitization occurs in herbivores when hepatic dysfunction or biliary obstruction impairs normal excretion of phylloerythrin in bile. Phylloerythrin, a photodynamic agent, is produced by chlorophyll contained in ingested plants by gastrointestinal bacteria of herbivores. Phylloerythrin is normally absorbed from the intestines, taken up by hepatocytes, and excreted in bile, using the same pathway as bilirubin. Thus hepatocellular dysfunction or biliary obstruction prevents normal excretion and allows high concentrations of phylloerythrin to accumulate in blood and cutaneous tissue. Most often, secondary photosensitization occurs in animals with chronic liver disease and loss of 80% or more of normal hepatic function, but it can also occur in animals with acute liver disease or inflammatory or obstructive disorders of the biliary tree. Mutant Corriedale sheep have an inherited inability to excrete conjugated bilirubin and are also susceptible to secondary photosensitization because phylloerythrin concentrations are increased in these sheep.

8.1.1.5.5.2.3

### Congenital porphyria.

Congenital porphyria is a metabolic disorder involving the liver that occurs in several species, including cattle and cats. This disorder is caused by abnormal metabolism of heme, leading to abnormal excretion and an accumulation of porphyrins, which are themselves photodynamic.

8.1.1.5.5.6

### Immunologic manifestations of hepatic failure

Chronic liver failure leads to an impairment of normal hepatic immune function. As a consequence, the affected patient frequently develops endotoxemia and an increased risk of systemic infection. For the most part, this impairment is manifest as a reduction of blood filtration by Kupffer cells, which is primarily a result of shunting of portal blood rather than reduced phagocytic activity of the Kupffer cells.

8.1.1.6

### GALLBLADDER STRUCTURE AND FUNCTION

The structure of the gallbladder and major ducts of the biliary system is similar in all species (the gallbladder is absent in the horse, the rat, and the elephant). It consists of a muscular wall (tunica muscularis) and a mucosa lined by simple columnar epithelium. The epithelium and muscularis are separated only by the lamina propria because the gallbladder lacks a muscularis mucosae. Right and left hepatic ducts carry bile from different lobes of the liver; these ducts and the cystic duct from the gallbladder unite to form the common bile duct. Location of the opening of the common bile duct into the intestine differs somewhat among the domestic species; it is as little as 2 cm from the pylorus in the pig to as much as 70 cm from the pylorus in the cow.

Fig. 8-29 **Bilobed gallbladder, liver, cat.** Bilobed gallbladders are developmental anomalies that have little or no clinical significance and are found most often in cats. (Courtesy College of Veterinary Medicine, University of Illinois.)

The gallbladder stores and concentrates bile. Considerable concentration (twentyfold to thirtyfold) of bile by active transport of sodium and anions across the gallbladder epithelial cells occurs in dogs and cats, whereas little concentration occurs in pigs and ruminants. The horse lacks a gallbladder and continuously releases bile into the duodenum.

416

417

Fig. 8-30 **Distended gallbladder, calf.** Note the distended gall bladder, which is common in all species following a prolonged period of fasting, because there is no stimulus for emptying the gallbladder. Thus they are frequently seen at necropsy of sick animals. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Developmental anomalies of the gallbladder may be most common in the cat, of bilobed and occasionally trilobed gallbladders can occur (Fig. 8-29). There is no reported clinical significance of these anomalies.

Animals that have not eaten in 24 to 48 hours or that are starving or cachectic can have notably enlarged gallbladders. The reason is that these animals lack the paracrine stimulus (i.e., cholecystokinin), and a number of other neural and hormonal stimuli, to contract the gallbladder and relax the sphincter at the termination of the common bile duct, which regulates flow of bile into the duodenum (Fig. 8-30).

### 8.1.2 EXOCRINE PANCREAS

#### 8.1.2.1 NORMAL ANATOMY

##### 8.1.2.1.1 Development

The embryonic origin of the pancreas begins as a dorsal and a ventral bud of the duodenum. These buds fuse during embryogenesis to give rise to the entire pancreas. The major pancreatic duct arises from fusion of the ventral duct and the distal portion of the dorsal duct.

##### 8.1.2.1.2 Structure

The pancreas is a lobulated, pink to gray, tubuloalveolar gland, a large portion of which is located in the mesentery immediately adjacent to the duodenum. The blood vessels, nerves, and lymph vessels that serve the pancreas are located within the delicate connective tissue septa that separate the lobules of pancreatic tissue. The pancreas contains both endocrine and exocrine elements, the endocrine portion being the islets of Langerhans. The exocrine portion constitutes the majority of the pancreas, up to 80% to 85% of the organ, and consists of acini composed of columnar to triangular secretory cells. The acinar cells have basally located oriented nuclei and cytoplasm with a deeply basophilic basal margin and eosinophilic, granular zymogen granules occupying the apical portion of the cytoplasm. When the cells are appropriately signaled, the zymogen granules, containing the digestive enzymes of the pancreas, are released into the lumen of the acinus. The ductal system, in which secretions of the exocrine pancreas are conveyed to the intestinal tract, commences as fine radicals within acini and progresses to intralobular and interlobular ducts. These small ducts eventually drain into the main pancreatic duct or ducts. The arrangement of the major pancreatic ducts and how they empty into the duodenum varies among the domestic species. It is particularly variable in the dog, in which at least five different anatomic arrangements are recognized. In the cat, the major pancreatic duct enters the duodenum in close proximity to the common bile duct, and this may predispose the cat to pancreatic injury.

##### 8.1.2.1.3 Normal Function

The exocrine pancreas produces secretions that contribute to digestion. The secretions contain a variety of enzymes that break down dietary lipids (lipase and phospholipase), proteins (trypsin and chymotrypsin), and carbohydrates (amylase). The secretions also contain electrolytes, which maintain the pH of the intestinal contents within a range that is optimal for enzymatic activity. Pancreatic enzymes act on the products of gastric digestion after they enter the duodenum. These enzymes often are released into secretions as inactive precursors (proenzymes), which helps prevent degradation of the pancreas by its own digestive enzymes. These are activated within the intestine. In addition, inhibitors of pancreatic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

enzymes are present in the pancreatic tissue. Secretion is controlled by neural stimulation regulated by the vagus nerve and by humoral factors. Secretin is one of the more important hormones involved in pancreatic secretion, and it stimulates water and bicarbonate secretion by duct cells. It is produced by neuroendocrine cells within the duodenal epithelium. The efflux of acid from the stomach and the presence of fatty acids in the duodenum stimulate its release. Cholecystokinin, another important hormone, stimulates the release of digestive enzymes from the acinar cells. It is produced by neuroendocrine cells of the duodenum in response to the presence of fatty acids, peptides, and amino acids.

8.1.2.1.4

### Consequences of Dysfunction of the Exocrine Pancreas

The exocrine pancreas has considerable functional reserve; thus only disorders that affect significant portions of this organ can cause the maldigestion that characterizes exocrine pancreatic insufficiency. Maldigestion as a consequence of exocrine pancreatic insufficiency is most common in the dog. In dogs pancreatic exocrine deficiency is usually the result of either exocrine pancreatic atrophy or chronic pancreatitis. However, pancreatic exocrine deficiency does occur sporadically in other species, including cats and in cattle, specifically calves with pancreatic hypoplasia. Exocrine pancreatic insufficiency in small animals and calves is clinically characterized by steatorrhea, diarrhea, and weight loss despite polyphagia. In contrast, horses with very little functional pancreatic tissue may develop hypoinsulinism, but rarely develop the clinical signs that characterize exocrine pancreatic insufficiency in other species.

8.1.2.2

### PORTALS OF ENTRY

Portals of entry into the exocrine pancreas are listed in [Box 8-1](#).

8.2

## DISEASES OF THE LIVER AND BILIARY SYSTEM

8.2.1

### DEVELOPMENTAL ANOMALIES AND INCIDENTAL FINDINGS

Developmental anomalies of the liver occur in domestic animals, although most are of little consequence.

8.2.1.1

### CONGENITAL BILIARY CYSTS

These cysts are found within the livers of dogs, cats, and pigs, but presumably all domestic species can be affected. The cysts are usually an incidental finding. They are usually single, have a thin wall lined by a single layer of biliary epithelium, and are filled with clear fluid. The predominant origin of congenital biliary cysts is thought to be through abnormal development of intrahepatic bile ducts. They can be found in animals of any age. Congenital cysts must be distinguished from parasitic cysts, particularly cysticerci, because they also have a thin wall and are fluid-filled. The presence of the larval cestode within parasitic cysts assists in distinguishing the two structures.

Cysts that occur within the liver of cats, pigs, and to a lesser extent dogs, which typically are multiple and affect extensive areas of the liver, are thought to be developmental anomalies of the intrahepatic bile ducts, although they are considered to be benign cystic biliary neoplasms by some ([Fig. 8-31](#)). Congenital

## Pathologic Basis of Veterinary Disease, 4th Edition

polycystic liver disease, characterized by numerous epithelial-lined cysts in the liver and kidneys, occurs in dogs. Cairn terriers and West Highland white terriers are predisposed to the disease as are cats, with Persian cats believed to have a higher risk for the disorder, and goats. Affected animals can die of either liver or renal failure.

8.2.1.2

### HEPATIC DISPLACEMENT

Displacement of the liver into the thoracic cavity, called a diaphragmatic hernia, can occur when there is a defect in the diaphragm. A congenital malformation that leaves an opening in the diaphragm or a traumatic event that ruptures the diaphragm can cause this condition.

8.2.1.3

### TENSION LIPIDOSIS

Discrete, pale areas of parenchyma at the liver margins are common in cattle and horses (Fig. 8-32). These foci typically occur adjacent to the insertion of a ligament (serosal) attachment, and it is proposed that these attachments impede blood supply to the subjacent hepatic parenchyma by exerting tension on the capsule. Affected hepatocytes most probably accumulate fat within their cytoplasm (lipidosis) as a consequence of hypoxia. The lesions are of no functional significance.

**Fig. 8-31 Biliary cysts, liver, pig.** Multiple biliary cysts within the liver of a pig. Unilocular cysts replace a portion of the parenchyma in the affected portion of the liver. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.2.1.4

### CAPSULAR FIBROSIS

418

Discrete fibrous tags or plaques are frequently present on the diaphragmatic surface of the liver and on the adjacent diaphragm of the horse (Fig. 8-33). Resolution of nonseptic peritonitis, possibly as a result of contact between the diaphragm and the adjacent liver capsule, rather than of parasitic nematode migration tracts, has been proposed as the cause of these regions of capsular fibrosis.

419

**Fig. 8-32 Tension lipidosis, liver, cut surface, cow.** Note the area of fatty infiltration (*F*), the ligamentous attachment adjacent to the affected portion (*arrowhead*), and the areas of telangiectasis (*arrows*). (Courtesy College of Veterinary Medicine, North Carolina State University.)

**Fig. 8-33 Capsular fibrosis, liver, horse.** Numerous fibrous tags are present on the diaphragmatic surface of the liver. These tags are thought to be attributed to reparative fibrosis of the migration tracts of *Strongylus* spp. larvae. (Courtesy College of Veterinary Medicine, North Carolina State University.)

### 8.2.1.5 POSTMORTEM CHANGE

Autolysis of the liver occurs rapidly and can be advanced before it is obvious in most other tissue. At or just before death, bacteria are released from the gastrointestinal tract into the portal circulation and reach the liver where they proliferate rapidly after death. This process is especially rapid in large animals during hot weather—particularly cattle, in which fermentation in the adjacent rumen produces heat—and in pigs, which are often well insulated by fat. Pale areas appear on the capsular surface as bacterial degradation begins. In time, the organ becomes green-blue as bacteria degrade blood pigments to iron sulfide. The liver in contact with the gallbladder is quickly discolored by bile pigment, which passes through the wall of the gallbladder. The consistency of the organ becomes puttylike and gas bubbles may form beneath the capsule and in the parenchyma from bacterial fermentation. Postmortem changes are covered in detail in [Chapter 1](#).

### 8.2.2 CIRCULATORY DISORDERS

#### 8.2.2.1 DISTURBANCES OF OUTFLOW

##### 8.2.2.1.1 Passive Congestion (Acute and Chronic)

Passive congestion of the liver can occur in any species and is almost always the consequence of cardiac dysfunction. Right side heart failure produces elevated pressure within the caudal vena cava that later involves the hepatic vein and its tributaries. Chronic passive congestion is particularly common in aged dogs and occurs secondary to endocardiosis (mucoid degeneration) of the right atrioventricular valve.

## Pathologic Basis of Veterinary Disease, 4th Edition

Acute passive congestion, on the other hand, can occur as a consequence of acute right side heart failure, which has a wide variety of causes.

The appearance of the liver differs with the duration and severity of the congestion. Passive congestion initially causes distention of central veins and centrilobular sinusoids. Persistent centrilobular hypoxia leads to atrophy or loss of hepatocytes and eventually to centrilobular fibrosis. Fibrosis of the central vein (phlebosclerosis) may also occur.

Acute congestion of the liver produces slight enlargement of the organ, and blood flows freely from any cut surface. The intrinsic lobular pattern of the liver may be slightly more pronounced, particularly on the cut surface, because centrilobular areas are congested (dark red) in contrast to the more normal color of the remainder of the lobule.

Diffuse enlargement and rounded edges of liver lobes are the main features of chronic passive congestion (Fig. 8-34). Chronic passive congestion leads to persistent hypoxia in centrilobular areas and, because of oxygen and nutrient deprivation, the centrilobular hepatocytes atrophy, degenerate, or eventually may undergo necrosis. As a result, sinusoids in these areas are dilated and congested and grossly appear red, whereas periportal hepatocytes frequently undergo lipidosis (fatty degeneration) because of hypoxia, thereby causing this area of the lobule to appear yellow. The result is accentuation of the lobular pattern of the liver, referred to as an enhanced lobular or reticular pattern. It is especially evident on the cut surface of the liver, and the enhanced lobular pattern that occurs with severe chronic passive congestion has been likened to the appearance of the cut surface of a nutmeg, and so is termed nutmeg liver (Fig. 8-35). This pattern is not unique to passive congestion, however, and is encountered with other processes, such as zonal hepatic necrosis. In addition to an enhanced lobular pattern, chronic passive congestion is characterized by focal fibrous thickening of the capsule, and, in severe cases, widespread hepatic fibrosis that bridges between central veins (Fig. 8-36).

419

420

**Fig. 8-34 Chronic passive congestion, liver, dog.** Chronic passive hepatic congestion in the liver of a dog with a heart base tumor that impeded venous return to the heart. The liver is enlarged with rounded margins. (Courtesy College of Veterinary Medicine, North Carolina State University.)

Fig. 8-35 **Chronic passive congestion (nutmeg liver), liver, cut surface, cow.** The congestion in the centrilobular areas and the peripheral lipid accumulation give the liver a characteristic appearance that has been likened to that of the cut surface of a nutmeg, hence the term *nutmeg liver*. *Inset:* Cut surface of a nutmeg for comparison. (**Figure**, Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University. **Inset**, Courtesy Dr. M.O. Howard, College of Veterinary Medicine, Iowa State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

**Fig. 8-36 Chronic passive congestion, liver, dog.** The liver is firm because of hepatic fibrosis that is most severe in centrilobular areas (*arrows*). The central vein is surrounded by a mild amount of connective tissue from which fine fibrous septa extend out into the lobule. Note the macrophages containing hemosiderin, the result of erythrocyte breakdown in this area as a result of chronic congestion. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

8.2.2.1.2

### Hepatic Veno-Occlusive Disease

Intimal thickening and occlusion of the central vein by fibrous connective tissue characterize the distinctive lesions of this syndrome. The consequence is passive hepatic congestion and resultant hepatic injury, which may progress to hepatic failure and its associated constellation of signs. The lesion is not etiologically specific but can follow pyrrolizidine alkaloid or aflatoxin-induced hepatic injury. An extremely high incidence is recognized in captive exotic cats, such as cheetahs, possibly because of the ingestion of large amounts of vitamin A, although the mechanism for this lesion is not known.

8.2.2.2

### DISTURBANCES OF BLOOD FLOW INTO THE LIVER

8.2.2.2.1

### Anemia

The centrilobular (periacinar) regions of the lobule receive blood last; thus it is the least oxygenated, and the effects of hypoxia are usually manifested first in this area. Acute severe anemia, regardless of cause, can cause centrilobular or paracentral degeneration and even necrosis of hepatocytes (Fig. 8-37). This typically occurs in severe anemias of precipitous onset. Chronic anemia can cause atrophy of centrilobular hepatocytes, which results in dilation, and congestion of sinusoids. Livers from animals with severe

420

421

## Pathologic Basis of Veterinary Disease, 4th Edition

anemia, whether acute or chronic, typically have an enhanced lobular pattern that is evident on both the capsular and cut surfaces of the organ (see description of enhanced lobular pattern later).

**Fig. 8-37 Centrilobular hepatocyte atrophy, liver, dog.** In chronic anemia, centrilobular hepatocytes, which are the last hepatocytes in the lobule to receive oxygenated blood, become atrophic, and as a consequence, their sinusoids are more dilated. C, Central vein. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

### 8.2.2.2.2

#### Congenital Portosystemic Shunts

A congenital portosystemic shunt is an abnormal vascular channel that allows blood within the portal venous system to bypass the liver and to drain into the systemic circulation. A congenital shunt can be either intrahepatic or extrahepatic in location but is usually limited to a single relatively large-caliber vessel ([Fig. 8-38, A](#)). A variety of different shunts have been described. Typically, intrahepatic portosystemic shunts involve failure of closure of the ductus venosus at birth. The ductus venosus is a normal fetal vessel that conducts blood from the portal vein to the caudal vena cava. These shunts, such as the ductus venosus, are most often located in the left side of the liver. This anomaly occurs most often in large breed dogs. Extrahepatic congenital shunts, such as portal vein to caudal vena cava anastomoses and portal vein to azygous vein anastomoses, occur more often in small breeds of dogs. Shunts have been described in several species but occur most commonly in the dog and cat. Affected animals are typically stunted and frequently develop signs of hepatic encephalopathy. The liver is small and may have a characteristic histologic appearance of lobular atrophy and reduplication of arterioles and small or absent portal veins within the portal tracts ([Fig. 8-38, B](#)). The portal vein pressure is normal in congenital shunts and ascites does not occur. Abnormal vascular anastomoses are often difficult to identify without benefit of antemortem imaging studies. Affected dogs frequently have abnormal plasma ammonia concentrations and, as a consequence, pass ammonium biurate crystals in their urine ([Fig. 8-39](#)). It should be noted that the liver has a stereotypic response to inadequate portal vein perfusion. Thus the histologic appearance of

## Pathologic Basis of Veterinary Disease, 4th Edition

congenital portosystemic shunts and other vascular anomalies of the liver (discussed later) have considerable overlap. Clinical data, such as the presence or absence of shunt vessels and the determination of portal vein pressure, may be necessary to achieve a final diagnosis.

**Fig. 8-38 Portosystemic shunts, liver, dog.** **A**, A single anomalous vessel that connects the portal circulation with the systemic circulation is the characteristic lesion of congenital portosystemic shunt. Note the small size but normal color of the liver (up under the rib cage). **B**, Congenital portosystemic shunt. Portal areas are abnormal because they lack a portal vein and contain numerous small-caliber arterioles. H&E stain. (**A**, Courtesy Dr. J. Sagartz, College of Veterinary Medicine, The Ohio State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

**Fig. 8-39 Ammonium biurate crystals, urinary bladder, dog.** The bladder contains ammonium biurate crystals. These crystals can result from abnormal ammonia metabolism in dogs with portosystemic vascular anastomoses. (Courtesy College of Veterinary Medicine, North Carolina State University.)

421

8.2.2.2.3

### Portal Hypertension

422

Increased pressure within the portal vein can arise from disturbances of venous blood flow in any of following three sites:

- Prehepatic
- Intrahepatic
- Posthepatic

Prehepatic portal hypertension is relatively uncommon and occurs when blood flow through the portal vein is impaired before it enters the liver. Portal vein thrombosis can be induced by damage to the portal vein, by local inflammatory disorders including pancreatitis, or by hypercoagulable states. Tumor emboli can also obstruct the portal vein. External compression by tumors or abscesses can restrict or obstruct portal vein flow as well. Portal vein hypoplasia affecting the extrahepatic segment of the portal vein is another cause.

Intrahepatic portal hypertension arises from increased resistance to blood flow to, or within, the sinusoids. Chronic liver disease that typically results in bridging collagenous septa, loss of normal lobular architecture, and regenerative nodule formation is the most common intrahepatic cause of portal hypertension. Sinusoidal fibrosis from diseases such as lobular dissecting hepatitis is another cause. Disorders such as veno-occlusive disease, amyloidosis, and schistosomiasis and other granulomatous disease processes can also produce intrahepatic portal hypertension. Arteriovenous fistulae (discussed later) within the hepatic parenchyma can also lead to intrahepatic portal hypertension.

Posthepatic causes of portal hypertension are uncommon and include any abnormalities that lead to increased resistance to venous outflow in the hepatic vein or adjacent vena cava. Partial or complete thrombosis of the hepatic veins (Budd-Chiari syndrome) or of the adjacent caudal vena cava are the most likely, although uncommon, causes of posthepatic portal hypertension. Congestive heart failure can lead to portal hypertension.

Regardless of cause, persistent portal hypertension can lead to acquired portosystemic shunts with the exception of passive congestion, which rarely, if ever, results in the development of shunt vessels. These shunts are usually numerous and composed of distended thin-walled veins, which may connect the mesenteric veins and the caudal vena cava (Fig. 8-40). Ascites is common in conditions that develop acquired shunts because of the associated portal hypertension.

8.2.2.2.3.1

### Vascular anomalies that may produce portal hypertension

8.2.2.2.3.1.1

#### Intrahepatic arteriovenous shunts (anastomoses).

Arteriovenous shunts, either acquired or congenital, occur in the dog and cat and are direct communications between the hepatic artery and branches of the portal vein. They may occur anywhere within the liver. Affected portions of the liver contain convoluted thick-walled arteries and distended portal vein branches. Shunting of blood may lead to portal hypertension or reversal of the direction of portal blood flow, subsequent development of acquired portocaval shunts and ascites. Clinical signs vary in intensity, most likely in relationship to the caliber of vessels that are affected, and are probably the result of the degree of portosystemic shunting of blood that results.

**Fig. 8-40 Acquired portosystemic anastomoses, abdomen, dog.**

Acquired portosystemic anastomoses secondary to portal hypertension (in this case as a consequence of chronic hepatitis in a dog). The numerous prominent veins that are present over the surface of the kidney allow blood within the portal venous system to bypass the liver and directly enter the systemic circulation. (Courtesy Dr. L. Hardy, College of Veterinary Medicine, North Carolina State University.)

8.2.2.2.3.1.2

**Portal vein hypoplasia (microvascular dysplasia, noncirrhotic portal hypertension).**

Portal vein hypoplasia is a congenital vascular anomaly that occurs in dogs and occasionally in cats. It is characterized by abnormally small extrahepatic or intrahepatic portal veins, which result in diminished hepatic perfusion by the portal vein blood flow and the potential for portal hypertension. Typically, affected animals have small livers and the typical histologic pattern of portal vein hypoperfusion, small or absent portal veins, proliferated hepatic arterioles (so-called reduplication), and hepatocyte atrophy. This disorder resembles portosystemic shunts histologically, but affected animals often have portal hypertension and resultant ascites. Portal fibrosis and biliary hyperplasia occur in about half of the cases. Because of the histologic similarities between portal vein hypoplasia and congenital portosystemic shunts, clinical data, such as imaging studies to determine the presence of a shunt vessel, are often required to make final diagnosis from biopsy material.

422

423

**Fig. 8-41 Telangiectasia, liver, cut surface, cow.** Telangiectasia is a condition in which hepatic sinusoids become dilated and filled with blood. These lesions can be seen as dark red areas on the cut and capsular surface of the liver. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### 8.2.2.3 INCIDENTAL VASCULAR DISORDERS

#### 8.2.2.3.1 Telangiectasis

Telangiectasis is the notable dilation of sinusoids in areas where hepatocytes have been lost. Grossly, these areas appear as variably sized dark blue foci within the liver that vary from pinpoint to several centimeters in size (Fig. 8-41). Telangiectasis is particularly common in cattle and apparently is of no clinical significance. It also occurs in old cats, in which it can be mistaken for vascular tumors such as hemangioma or hemangiosarcoma. Histologically, there is ectasia of the sinusoidal space and a loss of hepatocytes. There is no evidence of inflammation or fibrosis associated with this lesion.

### 8.2.2.4 INFARCTION

Infarction of the liver occurs infrequently because of the organ's dual blood supply from the hepatic artery and portal vein. Infarcts are usually sharply delineated and may be either dark red when acute or pale as they age. They tend to occur at the margins of the liver, the terminal end of parenchymal perfusion, and can affect small wedges of only a few centimeters in length or larger portions of a lobe. Histologically, infarcted liver is characterized by a zone of coagulative necrosis bordered by a basophilic band of inflammatory cells and an outer band of hyperemia (Fig. 8-42). Torsion of individual lobes of the liver, which occurs infrequently, can result in vascular occlusion and infarction of the affected lobe.

Fig. 8-42 **Hepatic infarction, liver, dog.** Hepatic infarction is uncommon and usually occurs at the margins of the liver where the terminal divisions of the blood supply are found. Infarction of the liver is characterized by a zone of coagulative necrosis (*N*) rimmed with inflammatory cells (*I*) and an outer zone of congestion (*C*) in the viable liver. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

### 8.2.3 METABOLIC DISTURBANCES AND HEPATIC ACCUMULATIONS

#### 8.2.3.1 HEPATOCELLULAR LIPIDOSIS OR FATTY LIVER (STEATOSIS)

Lipids are normally transported to the liver from adipose tissue and the gastrointestinal tract in the form of either free fatty acids or chylomicrons, respectively. Within hepatocytes, free fatty acids are esterified to triglycerides that are complexed with apoproteins to form low-density lipoproteins, and these are released into the plasma as a readily available energy source for use by a variety of tissues. Some oxidation of fatty acids for energy production occurs within hepatocytes, and some fatty acids are converted to phospholipid and cholesterol esters. With the exception of ruminants, the liver also actively produces lipids from amino acids and glucose.

The presence of excessive lipid within the liver is termed hepatocellular lipidoses (steatosis) or fatty liver and occurs when the rate of triglyceride accumulation within hepatocytes exceeds either their rate of metabolic degradation or their release as lipoproteins. Hepatocellular lipidoses is obviously not a specific disease entity but can occur as a sequel to a variety of perturbations of normal lipid metabolism. The potential mechanisms responsible for excessive accumulation of fat within the liver include the following:

## Pathologic Basis of Veterinary Disease, 4th Edition

---

- |   |            |
|---|------------|
| 1. Excessive entry of fatty acids into the liver, which occurs as a consequence of excessive dietary intake of fat or increased mobilization of triglycerides from adipose tissue because of increased demand (e.g., lactation, starvation, and endocrine abnormalities). | 423<br>424 |
|---|------------|
- 
2. Abnormal hepatocyte function leads to accumulation of triglycerides within hepatocytes as a result of decreased energy for oxidation of fatty acids within hepatocytes.
  3. Excessive dietary intake of carbohydrates results in the synthesis of increased amounts of fatty acids with formation of excessive triglycerides within hepatocytes.
  4. Increased esterification of fatty acids to triglycerides in response to increased concentrations of glucose and insulin, which stimulate the rate of triglyceride synthesis from glucose or from prolonged increases in dietary chylomicrons.
  5. Decreased apoprotein synthesis and subsequent decreased production and export of lipoprotein from hepatocytes.
  6. Impaired secretion of lipoprotein from the liver because of secretory defects produced by hepatotoxins or drugs.

It must be stressed that these are potential mechanisms (some being more significant than others, depending on the condition of the animal) and that more than one defect might occur in any given hepatic disorder. Regardless of cause, the gross appearance of the hepatocellular lipidoses is highly characteristic. With progressive accumulation of lipid, the liver enlarges and becomes yellow (Fig. 8-43, A). In mild cases, lipids may only accumulate in specific portions of each lobule, such as centrilobular regions, thereby imparting an enhanced lobular pattern to the liver. In extreme cases, the entire liver is affected, and the organ may become considerably enlarged and have an extremely greasy texture. Lipid vacuoles are readily detected within the cytoplasm of hepatocytes (Fig. 8-43, B).

Specific causes and syndromes of hepatocellular lipidoses in domestic animals include the following:

1. Dietary causes of hepatocellular lipidoses include simple dietary excess in monogastric animals, such as a high-fat and/or high-cholesterol diet. Hepatocellular lipidoses is especially common in ruminants with high-energy demands, such as those in peak lactation or late gestation, and reflects increased entry of lipids into the liver as a result of increased mobilization of lipids from adipose tissue. Obese animals are particularly predisposed to develop hepatocellular lipidoses, such as occurs when dietary intake is restricted. Deficiencies of cobalt and vitamin B<sub>12</sub> have been implicated as causes of fatty liver in sheep and goats.
2. Toxic and anoxic causes of hepatocellular lipidoses are common. Sublethal (reversible) injury to hepatocytes frequently results in accumulation of lipid within the affected cell. Injury to hepatocytes can lead to accumulation of lipids because of decreased formation and/or export of lipoproteins by hepatocytes and decreased oxidation of fatty acids within hepatocytes.
3. Ketosis is a metabolic disease that results from impaired metabolism of carbohydrate and volatile fatty acids. In times of energy demand, free fatty acids are released from body fat stores, and the free fatty acids are esterified into fatty acyl CoA in the liver. Ketone bodies (acetoacetic acid and  $\beta$ -hydroxybutyric acid) are derived from fatty acyl CoA by oxidation in the mitochondria. In pregnant and lactating animals, there is a continuous demand for glucose and amino acids, and ketosis results

## Pathologic Basis of Veterinary Disease, 4th Edition

---

when fat metabolism, which occurs in response to the increased energy demands, becomes excessive. 424

Ketosis is characterized by increased concentrations of ketone bodies in blood (hyperketonemia), hypoglycemia, and low concentrations of hepatic glycogen. Ketosis is common in ruminants and usually occurs during peak lactation, whereas ketosis of sheep usually occurs in late gestation, particularly in ewes carrying twins; this latter disease is known as pregnancy toxemia. 425

4. Bovine fatty liver syndrome, also known as fatty liver disease, is mechanistically similar to ketosis. In dairy cattle, the disease is usually encountered in obese animals within a few days after parturition and is often precipitated by an event that causes anorexia, such as retained placenta, metritis, mastitis, abomasal displacement, or parturient paresis. Typically, affected beef cattle are obese and the disease occurs within a few days before parturition. Accumulation of lipid within the liver is the result of both increased mobilization of lipids from adipose tissue, which results in increased influx of fatty acids to the liver, and defective hepatocytic function, which results in decreased export of lipoprotein from the liver.
5. Feline fatty liver syndrome is a distinct syndrome of idiopathic hepatocellular lipidosis recognized in cats. Typically affected cats are obese and anorectic and have no other diseases that could cause hepatocellular lipidosis. Cats with this type of hepatocellular lipidosis frequently develop hepatic failure, icterus, and subsequently hepatic encephalopathy.
6. Hepatocellular lipidosis occurs in ponies, miniature horses, and donkeys. Shetland ponies are predisposed. The condition usually occurs in overweight pregnant or lactating mares, characteristically after an event that causes stress or anorexia. In addition to notable hepatocellular lipidosis, affected ponies are usually hyperlipemic and may also manifest signs of renal failure and hepatic rupture. In severe cases, hepatic encephalopathy and/or terminal disseminated intravascular coagulation can occur.
7. Endocrine disorders, such as diabetes mellitus and hypothyroidism, can produce hepatocellular lipidosis in a variety of species. In these cases, hepatocellular lipidosis is obviously but one manifestation of abnormal metabolism. The accumulation of lipids in the liver in the diabetic animal is the result of increased fat mobilization and decreased use of lipids by injured hepatocytes.

Fig. 8-43 **Fatty liver syndrome (hepatic lipidosis).** **A**, Cut surface, cow. The liver is swollen and yellow because of notable infiltration of lipid into hepatocytes. **B**, Steatosis or fatty degeneration, cat. Diffuse cytoplasmic accumulation of lipid is evident within the hepatocytes throughout the liver. H&E stain. ### 8.2.3.2

#### GLYCOGEN ACCUMULATION

Glucose is normally stored within hepatocytes as glycogen and is often present in large amounts after feeding. Excessive hepatic accumulation of glycogen occurs with the metabolic perturbations involving

## Pathologic Basis of Veterinary Disease, 4th Edition

glucose regulation, including diabetes mellitus and the glycogen storage diseases. In these instances, hepatic involvement is just one manifestation of a systemic disease process.

Glucocorticoid-induced hepatocellular degeneration is a specific disorder characterized by excessive hepatic accumulation of glycogen (Fig. 8-44, *A*). Excessive amounts of endogenous or exogenous glucocorticoids cause extensive swelling of hepatocytes from the accumulation of glycogen. Glucocorticoids induce glycogen synthetase and so enhance hepatic storage of glycogen. Glycogen accumulation leads to pronounced swelling of hepatocytes (up to 10 times normal volume), particularly those in the midzonal areas (Fig. 8-44, *B*). In severe cases of glucocorticoid-induced hepatocellular degeneration (often referred to as steroid-induced hepatopathy), the liver is enlarged and pale but otherwise unremarkable. The disorder occurs in dogs, and frequently is iatrogenic, but can also be a consequence of hyperadrenocorticism. The diagnosis can be confirmed on the basis of the characteristic microscopic appearance of the liver and identification of the source of the excess glucocorticoids.

425

426

**Fig. 8-44 Glucocorticoid-induced hepatopathy, liver, dog. A,** In dogs with glucocorticoid excess (Cushing's disease) from endogenous or exogenous sources, an extensive accumulation of glycogen in hepatocytes results in an enlarged, pale-brown to beige liver. Note also the pulmonary edema. **B,** Note the swollen hepatocytes (*arrows*) with extensive cytoplasmic vacuolation from glycogen accumulation. H&E stain. (*A*, Courtesy Dr. K. Bailey, College of Veterinary Medicine, University of Illinois. *B*, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.2.3.3

### AMYLOIDOSIS

Hepatic amyloidosis occurs in most species of domestic animals. Amyloidosis is not a single disease entity but a term used for various diseases that lead to the deposition of proteins that are composed of  $\beta$ -pleated sheets of nonbranching fibrils. Affected livers are enlarged, friable, and pale (Fig. 8-45, *A*). Histologically, hepatic amyloid appears as bright eosinophilic amorphous deposits that are usually found in the space of Disse along the sinusoids but can be found in the portal tracts and within blood vessel walls (Fig. 8-45, *B*). Amyloid's physical properties are responsible for its birefringence and characteristic apple green appearance in Congo red stained sections viewed under polarized light. As many as 15 distinct amyloid proteins have been identified, but the hepatic amyloid is usually derived from one of three types. In primary amyloidosis, the amyloid fibril is designated AL (amyloid light chain) and is composed of immunoglobulin light chains derived from the amino terminal variable region of  $\kappa$ - and  $\lambda$ -light chains synthesized by plasma cell neoplasms. Secondary or reactive amyloidosis occurs as a consequence of prolonged inflammation, such as chronic infection or tissue destruction. In secondary amyloidosis, by far the most common type to occur in veterinary medicine, the fibrils are composed of amyloid A (AA). The precursor protein is serum amyloid-associated (SAA) protein, an apolipoprotein which is an acute phase protein synthesized by the liver. Inherited or familial amyloidosis is uncommon in animals but occurs in Shar-Pei dogs and Abyssinian, Siamese, and other Oriental breeds of cats.

**Fig. 8-45 Hepatic amyloidosis, liver. A**, Cut surface, duck. Hepatic amyloidosis has imparted a firm, waxy appearance and a pale brownish hue to the affected liver. **B**, dog. The perisinusoidal spaces of Disse adjacent to the sinusoids are lined with a glassy eosinophilic (hyaline) material—amyloid. H&E stain. (*A*, Courtesy Drs. J. King and L. Roth, College of Veterinary Medicine, Cornell University. *B*, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Regardless of its cause, amyloid can accumulate in more than one pattern. It may accumulate in vessel walls in the portal area, within the connective tissue of the portal area, and in the space of Disse, where it impairs the normal access of plasma to hepatocytes. Amyloid deposits can produce varying degrees of hepatomegaly, and extensive accumulations cause the liver to appear pale. In severe cases, affected animals may have clinical signs of either hepatic dysfunction or failure because the liver is more fragile; liver rupture and exsanguinations may occur, especially in the horse. Frequently, amyloid is also deposited within the kidneys, particularly the glomeruli. Renal failure often occurs before signs of hepatic dysfunction are manifested.

8.2.3.4

### COPPER ACCUMULATION

Copper poisoning is included as a metabolic disorder because hepatic injury in copper poisoning of domestic animals frequently is the result of progressive accumulation of copper within the liver. This occurs in domestic animals, especially sheep, in which storage of copper is poorly regulated. Also, hereditary disorders of copper metabolism have been described in dogs.

Copper is an essential trace element of all cells, but even a modest excess of copper can be life threatening because copper must be properly sequestered to prevent toxicosis. Normally, serum copper is bound to ceruloplasmin and hepatic copper is bound to metallothionein. In cases of excess, the copper distribution is initially diffuse throughout the hepatic cytoplasm, but in later stages it is concentrated within lysosomes. Excess copper, like excess iron, can lead to the production of reactive oxygen species that initiate destructive lipid peroxidation reactions that affect the mitochondria and other cellular membranes. In domestic animals, copper toxicosis usually occurs as a consequence of one of the following:

1. Simple dietary excess in ruminants, particularly sheep, and pigs occurring, for example, because of excessive dietary supplementation as an overcorrection for copper deficiency or from contamination of the pasture with copper from sprays or fertilizer. It also occurs in sheep that have access to copper-containing mineral blocks formulated for cattle. 426  
427
2. Grazing animals on pastures with normal concentrations of copper but with inadequate concentrations of molybdenum, which antagonizes copper uptake.
3. Pasturing herbivores on fields with plants that contain hepatotoxic phytotoxins, usually pyrrolizidine alkaloids. *Heliotropium*, *Crotalaria*, and *Senecio* species are common examples of such plants. Pyrrolizidines prevent hepatocellular proliferation by their toxic action on the spindle during mitosis. This failure to replace necrotic hepatocytes leads to an ever-increasing copper load in surviving hepatocytes because these hepatocytes take up the copper released by the dying cells. Copper is excreted in the bile, and hepatic diseases that result in cholestasis are particularly likely to produce excessive accumulation of copper within the liver, even when dietary intake of copper is not excessive.
4. Hereditary disorders of copper metabolism, as occur in Dalmatians and Bedlington and West Highland white terriers. The disorder is best characterized in Bedlington terriers that have an autosomal recessive inheritance that leads to impaired biliary excretion of copper, which results in progressive accumulation within the liver.

The consequences of excessive accumulation of copper within the liver of domestic animals are species-dependent. In ruminants, particularly sheep, copper accumulates within the liver over a period of time (for one of the first three reasons listed previously), but some event triggers a sudden release of copper, which is followed by acute, severe intravascular hemolysis and hepatocellular necrosis, mostly because of

## Pathologic Basis of Veterinary Disease, 4th Edition

acute anemia. Necrosis of the liver is extensive and affects centrilobular and midzonal regions most consistently because of hypoxia, but massive necrosis can occur in severe cases. Despite the acute and fulminant nature of the terminal event, this process is referred to as chronic copper poisoning to distinguish it from disease caused by simple copper intoxication that causes gastroenteritis. In contrast, copper continues to accumulate in the livers of Bedlington terriers shown to have a mutation (deletion of exon 2) or mutations in the *MURR1* gene, which encodes a chaperone protein involved in copper excretion by hepatocytes. Copper accumulates in the centrilobular regions of the liver and leads to ongoing necrosis of hepatocytes, chronic inflammation, replacement fibrosis, and eventually to an end-stage liver and signs of hepatic failure (Fig. 8-46). Excessive concentrations of hepatic copper may be present in other breeds of dog including the Dalmatian, West Highland white terrier, Skye terrier, Doberman pinscher, American and English cocker spaniel, and Labrador retriever, although the significance or role of copper in the hepatic disease of these breeds of dog is uncertain. These diseases are discussed in the section on canine chronic hepatitis.

**Fig. 8-46 Hepatic copper, liver, dog.** The red-brown copper-containing granules are indicative of excess copper in the lysosomes of hepatocytes. Copper is not readily visible with H&E staining but can be confirmed by special stains. Rhodanine stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

8.2.3.5

### PIGMENT ACCUMULATION

Pigments are colored substances, some of which are normal cellular constituents, whereas others accumulate only in abnormal circumstances. They are covered in detail in [Chapter 1](#).

8.2.3.5.1

#### Bile Pigments

Bile pigments may accumulate in excessive amounts as a consequence of either extrahepatic or intrahepatic cholestasis and typically produce icterus and green discoloration of the liver.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 8.2.3.5.2

#### Hemosiderin

Hemosiderin is an iron-containing, golden-brown, granular pigment derived from ferritin, the initial iron-storage protein. As iron accumulates within the cell, aggregates of ferritin molecules form hemosiderin (Fig. 8-47). Most hemosiderin in Kupffer cells and other macrophages located in tissues throughout the body is derived from the breakdown of erythrocytes, whereas most hepatocellular hemosiderin is derived from iron present in transferrin and to a lesser extent hemoglobin. Hemosiderin forms in the liver when there is local or systemic excess of iron, such as when erythrocytic breakdown is excessive (e.g., hemolytic anemia), and within areas of hepatic necrosis. An excessive systemic load of iron that is characterized by abundant hemosiderin in a variety of tissues without impairment of organ function is called hemosiderosis. In contrast, hemochromatosis is an abnormally increased storage of iron within the body that can cause hepatic dysfunction. Notable accumulation of iron can produce a dark brown or even a black liver.

427

428

**Fig. 8-47 Hemosiderosis, liver, dog.** Dark blue granules, indicative of iron, stored as hemosiderin in hepatocytes are confirmed by the Prussian blue reaction. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

### 8.2.3.5.3

#### Lipofuscin

Lipofuscin is an insoluble pigment that is yellow-brown to dark brown and is derived from incomplete oxidation of lipids, such as those in cell membranes (Fig. 8-48). Lipofuscin is progressively oxidized with time; thus it actually is a group of lipid pigments, all of which consist of polymers of lipid, phospholipids, protein (and minimal carbohydrate in early forms). Amounts of lipofuscin present in the liver tend to increase with age.

Fig. 8-48 **Lipofuscinosis, liver, dog.** Lipofuscin can be detected by a variety of special stains. In these hepatocytes, lipofuscin granules in lysosomes are dark gray-blue to green. Schmorl's stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

### 8.2.3.5.4

#### Melanin

Melanin is an endogenous pigment that is dark brown or black. Benign disorders of melanin pigmentation are usually designated as melanosis. Congenital melanosis of the liver occurs in pigs and ruminants and produces variably sized areas of discoloration of the liver. Acquired “melanosis” of sheep has been described in Australia and is associated with the ingestion of certain plants, but the pigment has not been proven to be melanin and may be derived from a component of the ingested plants.

### 8.2.3.5.5

#### Parasite Hematin

Liver flukes specifically produce very dark excreta that contain a mixture of iron and porphyrin. These excreta produce the characteristic discoloration that occurs in fascioliasis (*Fasciola hepatica*), and is especially pronounced in the migratory tracts produced by *Fascioloides magna* in bovine livers.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.4 INFECTIOUS DISEASES OF THE LIVER

#### 8.2.4.1 VIRAL DISEASES

##### 8.2.4.1.1 Infectious Canine Hepatitis

Infectious canine hepatitis is, as the name implies, a viral infection of the liver of dogs and other canids, including foxes and coyotes, that produces acute necrosis and inflammation. The disease is caused by canine adenovirus 1. The majority of infections are asymptomatic, and infections that result in disease may not be fatal. The virus has a predilection for hepatocytes, vascular endothelium, and renal epithelium; fulminant disease is characterized by hepatic necrosis and widespread hemorrhage that can affect a variety of organs.

Exposure of susceptible dogs is most often via the oral route by contact with urine from infected dogs. Viremia last for 4 to 8 days, but virus is shed in the urine of infected dogs for prolonged periods. Virus multiplication initially occurs in the tonsils and produces tonsillitis with spread to local lymph nodes and then to the systemic circulation via the thoracic duct. Viremia is associated with leukopenia and fever. Spread of virus to the liver, endothelial cells, and mesothelial cells follows. Infection of Kupffer cells may precede hepatocytic injury. Adenoviruses are cytolytic and cause necrosis of infected cells.

Lesions of infectious canine hepatitis include widespread petechiae and ecchymoses, accumulation of clear fluid in the peritoneal and other serous cavities, the presence of fibrin strands on the surface of the liver, and enlargement and reddening of the tonsils and lymph nodes (Fig. 8-49, A). The liver is moderately enlarged and friable and may contain small foci of hepatocellular necrosis centered on centrilobular areas. An enhanced lobular pattern is sometimes evident because of the centrilobular hepatic necrosis. Characteristically the wall of the gallbladder is thickened by edema.

428

429

The severity of microscopic lesions present in individual dogs may reflect the duration of the disease. Susceptible puppies rapidly succumb to infection and have only scattered foci of hepatocellular necrosis, whereas fulminant disease in older dogs often produces both randomly scattered foci of hepatocellular necrosis and widespread centrilobular necrosis. The predilection for centrilobular necrosis is more likely to be related to the virus's penchant for infection and necrosis of endothelial cells that may lead to vascular stasis and local hypoxia than to any increased propensity for the virus to damage centrilobular hepatocytes. Large amphophilic intranuclear inclusions are found in vascular endothelium and hepatocytes (Fig. 8-49, B). Zonal necrosis may reflect ischemic injury and not direct virus-mediated destruction of hepatocytes. Virus-induced endothelial damage may lead to disseminated intravascular coagulation and hemorrhagic diathesis, which contribute to the hemorrhage observed in affected dogs. Some dogs recovering from infectious canine hepatitis develop an immune-complex uveitis (type III hypersensitivity), which produces degeneration and necrosis of the corneal endothelium and resultant corneal edema clinically known as “blue eye.”

Fig. 8-49 **Infectious canine hepatitis, hepatic necrosis, liver, dog.** **A**, The liver from a dog infected with infectious canine hepatitis (ICH) can be slightly enlarged and friable with a blotchy yellow discoloration. Sometimes fibrin is evident on the capsular surface. Note the petechiae on the serosal surface of the intestines caused by vascular damage from canine adenovirus type I infection. **B**, Infection of hepatocytes and endothelial cells with canine adenovirus type I produces characteristic basophilic intranuclear inclusions surrounded by a clear zone that separates them from the marginated chromatin (*arrow*). H&E stain. (**A**, Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

### Herpesvirus Infections

Herpesvirus infections of the liver typically occur in neonates or fetuses. A variety of abortigenic herpesviruses are described, each animal species being affected by a specific virus. Examples of these viruses include the abortigenic equine herpesvirus (equine herpesvirus 1), infectious bovine rhinotracheitis virus (bovine herpesvirus 1), caprine herpesvirus, canine herpesvirus (canine herpesvirus 1), feline viral rhinotracheitis virus, and pseudorabies virus.

Infection can occur via several routes, including transplacental exposure, passage through the birth canal, contact with infected littermates, and contact with oronasal secretions from the dam. In neonates, initial infection often occurs in the oronasal epithelium where virus replication first takes place. After local replication, the virus enters the blood stream via infected mononuclear phagocytic cells. Viremia leads to dissemination of the virus to a variety of organs, and viral infection is cytolytic.

The abortigenic herpesviruses characteristically induce multifocal, randomly distributed, small (<1 mm) areas of necrosis in several fetal organs, including the liver (Fig. 8-50, A). Similar lesions occasionally are present in neonates infected with herpesviruses.

Histologically, herpesvirus can produce multifocal hepatic necrosis with scant inflammation in fetuses and neonates (Fig. 8-50, B). The liver is often affected, but foci of necrosis are more consistently present in the kidneys, lungs, and spleen. The virus most often affects neonates in the first 2 weeks of life and is most severe before they develop competent thermoregulation. Animals that are able to maintain a normal body temperature are less likely to be affected.

429

430

Fig. 8-50 **Equine herpesvirus hepatitis, hepatic necrosis, liver, foal. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.2.4.1.3

### Rift Valley Fever

This is an acute, arthropod (mosquito)-transmitted zoonotic viral disease that principally affects ruminants, causing extensive mortality among calves and lambs, and abortion of pregnant ewes and cows. The causative virus is a member of the family Bunyaviridae, genus *Phlebovirus*. The disease occurs throughout much of Africa, and it is especially prevalent after periods of unusually high rainfall.

Hepatic involvement is consistently present in fulminant cases, typically in neonates, and is characterized by hepatic enlargement and yellow-orange discoloration. Areas of congestion may be present. In older animals, pale foci of hepatocellular necrosis that are randomly scattered throughout the parenchyma impart a mottled appearance and sometimes an enhanced lobular pattern because of the centrilobular hepatic necrosis. Diffuse petechiae and ecchymoses are also characteristic of the disease, as are edema and hemorrhages of the wall of the gallbladder. Disseminated intravascular coagulation probably contributes to the hemorrhagic diathesis and perhaps to the development of zonal hepatic necrosis.

**Fig. 8-51 Focal hepatic necrosis, Rift Valley fever, liver, sheep.** This disease produces randomly distributed focal areas of necrosis in the liver of lambs and fetuses, often with a central area of older necrosis surrounded by a rim of hepatocytes, which have been killed at a later stage in the infection. H&E stain. (Courtesy Armed Forces Institute of Pathology.)

Microscopic lesions are characterized by the presence of both randomly distributed foci of hepatocellular necrosis and more widespread zonal necrosis, which ranges from centrilobular to massive (Fig. 8-51). These lesions, particularly random hepatic necrosis, are more severe and widespread in young animals and aborted fetuses. Eosinophilic intranuclear inclusion bodies may be present in degenerate hepatocytes in areas of necrosis.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.2.4.1.4

### Wesselsbron Disease

This disease, like Rift Valley fever, is a zoonotic arthropod (mosquito)-transmitted viral disease that occurs in Africa; the virus occasionally causes disease in newborn lambs and abortion in ewes. The causative agent is a member of the Flaviviridae. Affected lambs have multifocal areas of hepatocellular necrosis, and icterus develops occasionally. Canalicular cholestasis may be apparent. Infected adult sheep usually survive infection, although they may develop focal areas of hepatocellular necrosis.

430

8.2.4.1.5

### Other Viral Infections

431

Certain viral diseases may involve the liver, but the hepatic involvement either does not occur invariably or it may be but one manifestation of a systemic process. Such diseases include feline infectious peritonitis that is characterized by foci of pyogranulomatous vasculitis or perivascular accumulations of lymphocytes and plasma cells within multiple organs, sometimes including the liver. Subacute and chronic forms of equine infectious anemia are characterized by cellular accumulations, particularly lymphocytes, in sinusoids and the space of Disse. Systemic adenoviral infection of lambs, calves, and goat kids may produce multifocal areas of hepatocellular necrosis, cholangitis, and necrosis of biliary epithelium. Porcine circovirus type 2 injures hepatocytes and Kupffer cells and can cause mild to severe necrosis.

8.2.4.2

## BACTERIAL DISEASES

8.2.4.2.1

### Liver Abscesses and Granulomas

Bacteria can reach the liver via a number of different routes and form abscesses (Figs. 8-52 through 8-54). Routes include the following:

- The portal vein
- The umbilical veins from umbilical infections in newborn animals
- The hepatic artery, as part of a generalized bacteremia
- Ascending infection of the biliary system
- Parasitic migration
- Direct extension of an inflammatory process from tissues immediately adjacent to the liver, such as the reticulum

Both gram-positive and gram-negative organisms can cause hepatic abscesses. In adult small animals, hepatic abscesses are often caused by *Yersinia* spp., *Nocardia asteroides*, and *Actinomyces* spp. Bacterial infections of the liver and subsequent formation of hepatic abscesses are especially common in feedlot cattle. This usually occurs as a sequel to toxic rumenitis because damage to the ruminal mucosa allows ruminal microflora, particularly *Fusobacterium necrophorum*, to enter the portal circulation. After initially localizing within the liver, bacteria proliferate and produce focal areas of hepatocellular necrosis and hepatitis that can, in time, develop into hepatic abscesses (Fig. 8-55). Liver abscesses of cattle

431

frequently are incidental lesions, but they can cause weight loss and decreased milk production. Less commonly, a hepatic abscess encroaches on the lumen of either a hepatic vein or the caudal vena cava. This can cause phlebitis that results in mural thrombosis, and because of the obstruction of the outflow to the venous drainage of the liver, passive congestion of the liver and portal hypertension can occur (Fig. 8-56). Detachment of portions of these mural thrombi can produce septic thromboemboli that lodge in the lungs. Rupture of hepatic abscesses directly into the hepatic vein or into the caudal vena cava occurs sporadically in cattle and may result in fatal septic embolization of the lungs. Sometimes death can be sudden from the blockage of large areas of pulmonary capillaries by the exudate. Hepatic abscesses derived from bacteria arriving via the portal vein may not be evenly distributed throughout the liver, possibly because of selective distribution of portal blood into different liver lobes, termed portal streaming. Occasionally, fungi such as *Mucor* sp. that proliferate in areas of ruminal ulceration invade the portal circulation and are carried to the liver and there cause extensive areas of necrosis and inflammation (Fig. 8-57).

**Fig. 8-52 Chronic hepatic abscesses, *Corynebacterium pseudotuberculosis*, liver, sheep.** Note the thick fibrous capsule and the pale caseous exudate characteristic of pus produced by *Corynebacterium pseudotuberculosis* in sheep. (Courtesy College of Veterinary Medicine, North Carolina State University.)

Fig. 8-53 **Hepatic abscesses, *Rhodococcus equi*, liver, goat.** Disseminated hepatic abscesses in a goat caused by *Rhodococcus equi*. This lesion is more commonly found in foals. (Courtesy Dr. P. Stromberg, College of Veterinary Medicine, The Ohio State University.)

Fig. 8-54 **Hepatic abscess, liver, cow.** An abscess in the liver is similar to those in other tissues and consists of an infiltrate of neutrophils, degenerating neutrophils, and necrotic tissue debris. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 8-55 **Hepatic abscess, *Fusobacterium necrophorum*, liver, cow.** Foci of necrosis and abscess formation. Abscesses such as this one can erode the wall of a hepatic vein or the caudal vena cava, rupture, and release their contents into the blood stream. (Courtesy Dr. P. Stromberg, College of Veterinary Medicine, The Ohio State University.)

Fig. 8-56 **Hepatic abscess, caudal vena cava, cow.** A hepatic abscess has eroded the wall of the vena cava, ruptured, and released its contents into the caudal vena cava. (Courtesy College of Veterinary Medicine, North Carolina State University.)

**Fig. 8-57 Multiple necrotic foci, disseminated fungal infection (*Mucor* spp.), liver, cow.** *Mucor* spp. enter the portal blood following ulcerative rumenitis and cause focal necrosis and inflammation in the liver. *Inset:* The hyphae of the causative organism (*pink*) are usually evident within the granuloma. Periodic acid–Schiff reaction. (**Figure**, Courtesy College of Veterinary Medicine, University of Illinois. **Inset**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Tuberculosis (*Mycobacterium bovis*) has been eradicated from almost all of the United States, but its occurrence in other countries varies with the effectiveness of control efforts. The primary site of the disease is pulmonary with subsequent dissemination to other organs including the liver. Other domestic animal species can be infected with *Mycobacterium bovis*, and it is also a zoonotic microbe. *Mycobacterium avium-intracellulare* complex can occur in domestic animals, especially dogs in the southern areas of the United States. Granulomas are randomly distributed (i.e., hematogenous spread) in the liver. They have a central core of cell debris, caseation, and granulomatous inflammation surrounded by a fibrous capsule (Fig. 8-58).

### 8.2.4.2.2

#### Bacillary Hemoglobinuria

Bacillary hemoglobinuria is an acute and highly fatal disease of cattle and sheep that occurs in various areas of the world, typically in those regions in which liver fluke (*Fasciola hepatica*) infection also occurs. Spores of *Clostridium haemolyticum*, the causative agent of bacillary hemoglobinuria, are ingested and come to reside within Kupffer cells, but they proliferate only in areas of low oxygen tension.

432

433

Migration of immature liver flukes, or less commonly other parasites, or an event such as liver biopsy produces a nidus of necrotic hepatic parenchyma in which bacterial spores can germinate. Bacteria proliferate and release toxins, the most important of which is phospholipase C, that induce the hepatocellular necrosis and intravascular hemolysis that characterize the disease. Grossly, these foci, which have been misnamed infarcts, are sharply delineated from the adjacent parenchyma, and usually are pale and surrounded by an intensely hyperemic zone (Fig. 8-59). Migration tracts of the immature flukes

## Pathologic Basis of Veterinary Disease, 4th Edition

that typically precipitate the disease may be present. Serous cavities (pleura, peritoneum, and pericardium) often contain excessive accumulation of red or straw-colored fluid that is sometimes flecked with fibrin. The liver contains one or more discrete foci of hepatic necrosis in which causative organisms may be visible in histologic sections. Affected animals have icterus, hemoglobinemia, and hemoglobinuria.

**Fig. 8-58 Multiple caseous granulomas, tuberculosis, *Mycobacterium bovis*, liver, cow.** Hepatic tuberculosis is characterized by random multifocal pale white to yellow caseous granulomas on the capsular and cut surfaces. (Courtesy Dr. M. Domingo, Autonomous University of Barcelona; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

8.2.4.2.3

### Infectious Necrotic Hepatitis

Also known as black disease, infectious necrotic hepatitis is most common in sheep and cattle but also occurs in pigs and horses. This disease is somewhat analogous to bacillary hemoglobinuria in that dormant spores of *Clostridium novyi* (usually type B) germinate in areas of lowered oxygen tension and release toxins that produce discrete foci of coagulation necrosis within the liver and eventually death of the host. Germination of spores is usually initiated by hepatic necrosis caused by the migration of immature liver flukes; however, a variety of other initiating factors that produce low oxygen tension within the liver parenchyma have been described. Parasitic migration tracts are usually present within the affected liver. Other lesions that may be present include diffuse venous congestion and accumulation of fluid within the pericardial sac and pleural and peritoneal cavities. Affected animals typically have one or more areas of hepatocellular necrosis, which usually manifests as discrete, pale areas of variable size. A zone of intense hyperemia often surrounds these foci. The carcass of affected animals typically putrefies rapidly because of high fever before death.

Fig. 8-59 **Focal hepatic necrosis, *Clostridium haemolyticum* (bacillary hemoglobinuria), liver, cut surface, cow.** These large areas of necrosis are sharply delineated from the adjacent parenchyma, are usually pale, and are surrounded by an intensely hyperemic zone of acute inflammation. (Courtesy Dr. J. King, College of Veterinary Medicine, Cornell University.)

### 8.2.4.2.4

#### Tyzzler's Disease

This disease is caused by *Clostridium piliforme* (formerly *Bacillus piliformis*), a gram-negative obligate intracellular parasite. It is well recognized in laboratory animals but occurs only sporadically in domestic animals. Infection is most common in foals, but has been described in calves, cats, and dogs and many other species. Typically, only very young or immunocompromised animals are affected. The bacteria are found in the intestinal tract of rodents. Infection is most likely through the oral route. The mechanisms of attachment and entry into host cells are unknown. After colonization of the gastrointestinal tract, organisms penetrate into the portal venous drainage and enter the liver. The disease is characterized by enlarged, edematous, and hemorrhagic abdominal lymph nodes, hepatic enlargement, and the presence of randomly distributed, pale foci of hepatocellular necrosis surrounded by a variably intense inflammatory infiltrate of neutrophils and mononuclear cells (Fig. 8-60, A). Diagnosis requires the demonstration of the characteristic, elongated large bacilli within viable hepatocytes at the margins of necrotic foci (Fig. 8-60, B). Silver stains, such as Warthin-Starry or Gomori's silver stain, are frequently used for this purpose (Fig. 8-60, C).

433

434

### Leptospirosis

This disease is caused by infection with the thin, spiral, motile bacterium of the genus *Leptospira*. There are several species, and each species consists of several serovars. Each serovar can differ with respect to the species affected, organs affected, and severity of disease. Leptospire enter the body through the mucous membranes or through the skin if its barrier functions have been disrupted. Contaminated water, bedding, and soil are common sources of infection, as the organism is shed in urine. Fetuses can develop transplacental infection. Infection can involve red blood cells, kidney, liver, and a number of other tissues depending on the infecting serovar. The liver is often involved in acute, severe leptospirosis of all domestic species. This is because a number of serovars cause intravascular hemolytic anemia leading to ischemic injury to centrilobular areas. Furthermore, organisms are present in large numbers in the liver, although the direct effects of leptospira toxins on hepatocytes are less well established.

**Fig. 8-60 Tyzzer's disease (*Clostridium piliforme*). A, Liver, horse.**

Disseminated gray-white 1- to 2-mm foci of necrosis surrounded by suppurative inflammation. **B, Foal.** *Clostridium piliforme* can be identified by the haphazard distribution of filamentous bacteria in the cytoplasm of hepatocytes. Giemsa stain. **C, Foal.** *Clostridium piliforme* can be readily seen with special stains such as Giemsa and Warthin-Starry stains. Warthin-Starry stain. (**A**, Courtesy Dr. R.C. Giles, University of Kentucky; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B** and **C**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Gross lesions include icterus when animals are infected with serovars that produce hemolysis. Hepatic hemorrhage and ascites can occur depending on the course of infection and the serovar involved. In some cases, acute infection can cause focal necrosis in addition to or instead of centrilobular necrosis. A common but nonspecific change in the liver of infected dogs is dissociation of hepatocytes. Affected cells become rounded and have eosinophilic granular cytoplasm and dark, shrunken hyperbasophilic nuclei. Bile casts in canaliculi are often apparent. Kupffer cells may contain abundant hemosiderin. Infection of dogs with *Leptospira grippotyphosa* has been reported to produce chronic (chronic-active) hepatitis, but it

## Pathologic Basis of Veterinary Disease, 4th Edition

is unlikely that leptospira are involved in the pathogenesis of the majority of spontaneous cases of chronic hepatitis.

### 8.2.4.2.6

#### Other Bacterial Infections

These diseases are grouped together because they all arise from a bacteremia that occurs during a systemic infection. A comprehensive list of systemic infections that may produce hepatocellular necrosis and hepatitis is beyond the scope of this chapter, but examples include *Yersinia pseudotuberculosis*, *Salmonella* spp. (lesions present within the liver are discrete accumulations of mixed mononuclear inflammatory cells, which often are referred to as “paratyphoid nodules”) and *Brucella* spp. infection in many species (Fig. 8-61, A and B). *Haemophilus agni* and *Pasteurella haemolytica* can present as infections in sheep. Other infections include *Arcanobacter pyogenes* (*Actinomyces pyogenes*) of the bovine fetus and neonate, *Campylobacter fetus* ssp. *fetus* in fetal and neonatal lambs, *Actinobacillus equuli* infection of neonatal foals, and *Nocardia asteroides* infection of dogs. *Yersinia tularensis* (*Francisella tularensis*), the cause of tularemia, can occur in cats and dogs. Bacterial infections such as these may produce lesions within the liver that range from small foci of hepatic necrosis to multiple, large abscesses. Determination of the specific causative agent is often dependent upon bacterial isolation and characterization.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

8.2.4.3

### PROTOZOAL DISEASES

The liver can be involved in systemic infections with *Toxoplasma gondii* or *Neospora* sp. Liver lesions are usually characterized by multifocal necrosis and inflammation. Inflammatory cells include neutrophils, macrophages, and smaller numbers of other inflammatory cells. Free tachyzoites or cysts containing bradyzoites can be found within necrotic areas or adjacent to them. Although there are subtle physical differences between the organisms, immunologic testing, such as immunohistochemical staining, is a more reliable means to separate the two organisms.

8.2.4.4

### DIMORPHIC FUNGAL DISEASES

Histoplasmosis is a fungal disease that is endemic in the United States and Canada and can occur occasionally in other areas. It is caused by *Histoplasma capsulatum*, a soil-dwelling organism. Dogs are affected most often. The route of infection is primarily through inhalation, although ingestion is also a possible route. In some circumstances pulmonary infections become disseminated and affect a variety of visceral organs, including the liver. Lesions in the liver consist of a multifocal distribution of granulomas with intralesional yeast forms of the organism. Numerous yeast forms can be found in the cytoplasm of macrophages and can be readily stained with the periodic acid–Schiff reaction. (Fig. 8-62, A and B).

8.2.4.5

### PARASITIC DISEASES

8.2.4.5.1

#### Nematodes

Migration of larvae through the liver is a common component of a nematode's life cycle in domestic animals. As larvae travel through the liver, they produce local tracts of hepatocellular necrosis that are accompanied by inflammation. These tracts are eventually replaced with connective tissue that matures into fibrous scars and which are especially prominent on the capsular surface (Fig. 8-63). These capsular scars appear as pale areas, and the term “milk spotted liver” has been used to describe livers in pigs scarred by migrating larvae of *Ascaris suum*. Larvae occasionally become entrapped within the liver or its capsule and are walled off within abscesses or granulomas. Examples of chronic hepatitis or hepatic scarring as a consequence of larval migration include migration of ascarids in several species of domestic animals, such as *Stephanurus dentatus* in pigs, and *Strongylus* sp. in the horse. Infection of the liver with adult nematodes is considerably less common than larval migration. *Capillaria hepatica* occasionally may be found in the hepatic parenchyma of dogs and cats.

Dogs with heartworm infection (*Dirofilaria immitis*) occasionally develop vena caval syndrome, also known as the postcaval syndrome, which is characterized by disseminated intravascular coagulation, intravascular hemolysis, and acute hepatic failure. The syndrome typically occurs in dogs with large numbers of adult worms in the vena cava and their more usual location within the right side of the heart and pulmonary artery (Fig. 8-64). The liver is engorged with blood as a consequence of severe passive congestion from the partial blockage of the caudal vena cava. It is proposed that mechanical factors produced by the presence of large numbers of worms in the right atrium or caudal vena cava are the cause of intravascular hemolysis, which characterizes vena caval syndrome, although other theories suggest that there may be a hypersensitivity reaction to antigens released by the worms.

435

436

The condition is rapidly fatal unless the nematodes are removed. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

8.2.4.5.2

### Cestodes

A number of cestodes occur within the hepatobiliary system of domestic animals. Those cestode parasites of greatest clinical significance develop encysted forms within the liver of the intermediate hosts. The most important are larval cestodes of the genus *Taenia*, adults of which inhabit the gastrointestinal tract of carnivores and which usually are innocuous to their definitive host. The ova ingested by an intermediate host develop into embryos, which penetrate the wall of the gut and then are distributed via the blood to virtually any site in the body. Parasitic cysts develop within the tissue of the intermediate host, and the life cycle of the parasite is completed when the cysts are ingested by the definitive host. Although the liver is but one organ in the intermediate host that may be affected, hepatic involvement is common because portal blood, in which embryos migrate, drains into the liver before flowing to the systemic circulation.

The adult cestode *Taenia hydatigena* shows up in dogs, whereas its intermediate stage, *Cysticercus tenuicollis*, appears in the peritoneal cavity of a variety of species, including horses, ruminants, and pigs (Fig. 8-65). Immature cysticerci migrate in the liver and can induce extensive damage if infection is heavy; lesions present are comparable to those induced by migration of immature *Fasciola hepatica*.

436

437

**Fig. 8-65 Cysticercosis, liver, cut surface, sheep.** The thick fibrous capsule usually indicates the death of the larva. (Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Hydatid liver disease is common in some countries. *Echinococcus granulosus* is a cestode that parasitizes canids as the definitive host, and hydatid cysts can develop in many different intermediate host animal species, including humans. The dog-sheep cycle is most important in many geographic areas. Pastured cattle are also commonly affected in other geographic locations. Adult worms in the intestines of dogs

## Pathologic Basis of Veterinary Disease, 4th Edition

pass proglottids into the dog's stool and thereby contaminate pastures. Ova are then ingested by sheep, cattle, or other species. Embryos may develop into hydatid cysts in virtually any organ in the intermediate host, but the liver and lungs are commonly affected. These cysts are usually less than 10 cm in diameter but can attain quite a spectacular size, particularly in humans. Hydatid cysts, even when present in large numbers, rarely cause overt clinical signs of disease in domestic animals.

Cestode adults occurring within the hepatobiliary system include *Stilesia hepatica*, *Stilesia globipunctata*, and *Thysanosoma actinoides*, all of which can inhabit the bile duct of ruminants. Infections with these parasites may result in chronic inflammation of the biliary tract, but they usually do not produce clinical signs of hepatic dysfunction.

### 8.2.4.5.3

#### Trematodes

Liver fluke disease of sheep and cattle, and occasionally other species, most commonly is caused by *Fasciola hepatica*. Hepatic fascioliasis occurs throughout the world in areas where climatic conditions, typically in low swampy areas, are suitable for the survival of aquatic snails, which serve as intermediate hosts for the parasites. Adult *Fasciola hepatica* are leaf-shaped parasites that inhabit the biliary system; their eggs pass via the bile to the intestinal tract and eventually are passed in the feces. Larvae then must develop in the snail intermediate host (genus *Lymnaea*). Cercariae that leave the snail, encyst on herbage where they develop into infectious metacercariae. Metacercariae are ingested by the ruminant host and penetrate the wall of the duodenum to enter the peritoneal cavity and subsequently enter the liver. They migrate within the liver before taking up residence within the bile ducts. Migration of immature flukes through the liver produces hemorrhagic tracts of necrotic liver parenchyma. These tracts are grossly visible and in acute infection are dark red, but with time become paler than the surrounding parenchyma. Repair is often by fibrosis. A variety of untoward sequelae can follow these migrations, including acute peritonitis; hepatic abscesses; death of the host as a consequence of acute, widespread hepatic necrosis produced by a massive infiltration of immature flukes; and the proliferation of spores of *Clostridium haemolyticum* or *Clostridium novyi* in necrotic tissue, which causes the subsequent development of bacillary hemoglobinuria or infectious necrotic hepatitis, respectively.

Mature flukes reside in the larger extrahepatic and intrahepatic bile ducts and cause cholangitis. Chronic cholangitis and bile duct obstruction lead to ectasia and stenosis of the ducts, and periductular fibrosis that thickens the walls so that the ducts become increasingly prominent. Obstruction of the ducts leads to cholestasis. Animals with chronic liver fluke disease are often in poor body condition.

*Fasciola gigantica* and *Fascioloides magna* are important causes of liver fluke disease of ruminants in some parts of the world. The adults of *Fasciola gigantica* and *Fasciola hepatica* reside in the bile ducts (Fig. 8-66). In contrast, adult *Fascioloides magna*, whose normal hosts are elk and white-tailed deer, reside in the hepatic parenchyma in aberrant hosts, such as cattle and sheep. In cattle, the immature *Fasciola magna* flukes cause extensive tissue damage as they migrate through the liver (Fig. 8-67), but the adults are enclosed by fibrous connective tissue in cysts containing a black fluid. In sheep and goats, the flukes continuously migrate through the liver, causing extensive damage and eventual death.

Other trematodes that may inhabit the bile ducts include *Dicrocoelium dendriticum* in horses, ruminants, pigs, dogs, and cats; *Eurytrema pancreaticum* and *Eurytrema coelomaticum* in ruminants; *Opisthorchis tenuicollis* in pigs, dogs, and cats, and *Opisthorchis viverrini* in dogs and cats; *Pseudamphistomum truncatum*, *Metorchis conjunctus*, *Metorchis albidus*, *Parametorchis complexus*, *Concinnum procyonis*, and *Platynosomum fastosum* in dogs and cats. All are capable of inducing changes similar to but usually

437

438

## Pathologic Basis of Veterinary Disease, 4th Edition

considerably milder than those caused by *Fasciola hepatica*. In addition, they occasionally cause obstruction of the biliary ducts.

**Fig. 8-66 *Fasciola hepatica* infection.** **A**, Chronic intrahepatic cholangitis (*Fasciola hepatica*), liver, cow. When *Fasciola hepatica* metacercariae are ingested, they migrate to the liver and then take up residence within the bile ducts. Mature flukes reside in the larger extrahepatic and intrahepatic bile ducts and cause chronic cholangitis and bile duct obstruction that lead to ectasia and stenosis of the ducts and periductular fibrosis that thickens the walls so that the ducts become increasingly prominent, as shown here. **B**, Adult *Fasciola hepatica*. Adult *Fasciola hepatica* are leaf-shaped flukes that inhabit the biliary system; their eggs pass via the bile into the intestinal tract and eventually are passed in the feces. (**A**, Courtesy Dr. K. Read, College of Veterinary Medicine, Texas A&M University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia. **B**, Courtesy Dr. T. Boosinger, College of Veterinary Medicine, Auburn University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Cats, and less often dogs, can develop pronounced chronic cholangitis from infections with flukes, most often Opisthorchiidae. Microscopically, larger intrahepatic bile ducts are dramatically thickened by concentric fibrosis and the duct lumen is usually dilated, often with papillary projections of biliary epithelium into the lumen (Fig. 8-68). A mild to moderate inflammatory infiltrate of neutrophils and macrophages is often found in and around the ducts, and the portal tracts are infiltrated by neutrophils, lymphocytes, and plasma cells. Eosinophils are generally uncommon. It is often difficult to detect adult flukes or ova in affected animals.

Fig. 8-67 **Fluke migration tracts, fascioloidiasis, liver, cow.** Migration of *Fascioloides magna* through the bovine liver produces extensive parenchymal damage. A black excretory pigment deposited by the fluke discolours the migration tracks black. (Courtesy Dr. J. Wright, College of Veterinary Medicine, North Carolina State University; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

Fig. 8-68 **Chronic intrahepatic cholangitis, liver, cat.** Fluke infections of the biliary tree of cats produce a characteristically pronounced periductular fibrosis, dilated bile duct, and papillary projections of biliary epithelium, although flukes may be difficult to find. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Dogs can be infected with the schistosome *Heterobilharzia americana*, which is normally a parasite in raccoons. Ova shed into water by infected raccoons release miracidia, which penetrate host snails. Dogs become infected when their skin is penetrated by cercariae, which are released from the intermediate snail hosts. Granulomatous lesions of the liver, and pancreas, intestines and mesentery result when ova released by adult schistosomes lodge in affected tissue and incite an inflammatory reaction.

### 8.2.5 INFLAMMATORY DISORDERS OF THE BILIARY TRACT

#### 8.2.5.1 NEUTROPHILIC CHOLANGITIS

Inflammation of the biliary ducts (either intrahepatic or extrahepatic) is termed cholangitis. There are several patterns of inflammation of the biliary tree that can be recognized. Neutrophilic (suppurative) cholangitis is the most common type of cholangitis. It is characterized by the presence of neutrophils within the lumen or the epithelium (Fig. 8-69). Acute and chronic forms of this process can occur. Rupture of affected bile ducts can lead to hepatic abscess formation. Most neutrophilic cholangitis is believed to be caused by ascending bacterial infections from the intestine.

#### 8.2.5.2 LYMPHOCYTIC CHOLANGITIS

This disorder occurs most often in cats. Affected cats are usually older than 4 years of age and often have icterus as a consequence of intrahepatic cholestasis. The inflammatory cells can involve bile ducts directly, making it difficult to identify the original bile duct within an affected portal tract, but usually the inflammatory cells are arrayed at the periphery of the ducts. Often by the time a biopsy is obtained, the liver is characterized by extensive aggregations of inflammatory cells, typically lymphocytes and plasma cells in portal tracts, particularly around numerous small bile ducts (Fig. 8-70). Inflammation usually is accompanied by bile duct proliferation, hepatic or biliary fibrosis, and intrahepatic cholestasis. The cause or causes of this syndrome are unknown. The disease might have an immunologic basis. Chronic lymphocytic cholangitis should be distinguished from suppurative cholangitis, which is caused most often by ascending bacterial infection of the biliary tree.

Fig. 8-69 **Suppurative cholangitis (intrahepatic), liver, cat.** This condition is characterized by the presence of degenerate neutrophils within the lumen or the walls of bile ducts in the portal areas. Ascending bacterial infection from the intestine via the common bile duct is the most common cause. H&E stain. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Fig. 8-70 **Feline lymphocytic cholangitis, liver, cat.** Large numbers of lymphocytes surrounding bile ducts and biliary hyperplasia in portal areas are the hallmarks of this disease. The inflammation most often affects the periphery of the bile ducts and could be termed a pericholangitis, but the syndrome is referred to as cholangitis. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 8.2.5.3 DESTRUCTIVE CHOLANGITIS

Destructive cholangitis is an uncommon syndrome characterized by necrosis of the epithelium of bile ducts (Fig. 8-71). Inflammation is often present around the areas of biliary destruction, but within the portal area. Certain chemicals, such as trimethoprim sulfa, have been implicated in this syndrome in dogs.

### 8.2.6 NUTRITIONAL DISEASES OF THE LIVER

#### 8.2.6.1 HEPATOSIS DIETETICA

Hepatositis dietetica (nutritional hepatic necrosis) is a syndrome of acute hepatic necrosis that occurs in young, rapidly growing pigs. This is but one manifestation of a variety of disorders that are likely to be, at least in part, caused by deficiency of vitamin E and/or selenium. The pathogenesis of hepatosis dietetica is incompletely defined. Although it is apparent that affected animals respond to the provision of vitamin E or selenium, it has been difficult, on an experimental basis, to produce the syndrome consistently by feeding diets deficient in vitamin E and selenium. Because vitamin E and selenium-containing enzymes are antagonists of free radical formation and are therefore important for the maintenance of stability and integrity of cellular membranes, it is believed that oxidative injury leads to hepatocyte necrosis.

439

440

**Fig. 8-71 Destructive cholangitis, liver, dog.** This condition is an uncommon disorder characterized by the destruction of bile duct epithelium, followed by regeneration in some instances. Necrotic or absent biliary epithelium, pigmented macrophages, and small numbers of mononuclear inflammatory cells in portal tracts are the typical histologic findings. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Regions of massive necrosis in the affected liver will initially be distended, deep red, and friable. Hepatosis dietetica is characterized by hemorrhagic centrilobular to massive hepatic necrosis (Fig. 8-72, *A and B*). The appearance of the liver reflects the extent of hepatic necrosis, the severity of the hemorrhage, and the duration of the deficiency. Later, in animals that survive the acute disease, parenchymal collapse and dense tracts of connective tissue (postnecrotic scarring) are usually evident.

8.2.6.2

### WHITE LIVER DISEASE

White liver disease derives its name from the pale, fatty livers in sheep that develop from a nutritional deficiency caused by insufficient cobalt intake. Animals grazing on soil that is depleted in cobalt either by natural deficiency or previous use of the area for plants, such as potatoes, that deplete soil of cobalt are affected. Cobalt is a necessary cofactor in the synthesis of vitamin B<sub>12</sub> and other enzymes. Deficiency of vitamin B<sub>12</sub> can lead to anemia, and the liver lesions may be attributed to the effects of anemia.

**Fig. 8-72 Massive necrosis, *Hepatositis dietetica*, liver, pig.** **A**, Areas of hemorrhagic centrilobular necrosis and massive necrosis appear as dark regions of different size scattered throughout the liver. **B**, Acute centrilobular necrosis is the principal lesion of this disorder. (**A**, Courtesy Dr. R. Michel, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy College of Veterinary Medicine, North Carolina State University; Dr. A.R. Doster, University of Nebraska; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.7 TOXIN-INDUCED LIVER DISEASE

The liver is subjected to toxic injury more often than any other organ. This is not surprising because the portal vein blood that drains from the absorptive surface of the intestinal tract flows directly to the liver. Thus the liver is exposed to virtually all ingested substances, including plant, fungal, and bacterial products, and metals, minerals, and other chemicals that are absorbed into the portal blood. Hepatotoxic injury can range along a spectrum from pure hepatocellular injury to pure biliary injury and a mixed pattern of injury that involves both components of the liver.

Hepatotoxic drugs can be divided into two basic categories. Predictable hepatotoxins are those that affect the large majority of animals that are exposed, and the effect is evident within a similar dose range. A partial list of predictable hepatotoxins is presented in [Table 8-1](#). The majority of recognized hepatotoxins in veterinary medicine fall into this category; carbon tetrachloride and pyrrolizidine alkaloids are examples of predictable hepatotoxins. Toxic injury, even with predictable toxins, is not always uniform, however. A variety of factors influence the severity of injury induced by a toxin; these factors include age, sex, diet, endocrine function, genetic constitution, and diurnal factors. It is therefore not surprising that responses of individual animals exposed to the same toxin can vary considerably.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 8-1 Common Hepatotoxic Plants of Veterinary Importance

Plant Family	Species Affected	Toxic Principle	Characteristic Injury	Miscellaneous
Compositae	Cattle, pigs	Carboxyatractyloside	Centrilobular necrosis	Hypoglycemia and ascites occur in acute intoxication in pigs.
<i>Xanthium</i> spp.				
Myoporaceae	Sheep, cattle, horses, pigs	Furanosquiterpenoid oils (ngaione)	Usually centrilobular to variable zonal necrosis	Sheep also develop pulmonary injury.
<i>Myoporum</i> spp.				
Verbenaceae	Cattle, sheep, occasionally goats	Triterpenes (lantadene A & B)	Megalocytosis, canalicular cholestasis, focal hepatocellular necrosis	Icterus and photosensitization is common. Renal and myocardial injury also occur.
<i>Lantana camara</i> , <i>Lippia</i> spp.				
Compositae	Pigs, horses, cattle, sheep, goats	Pyrrolizidine alkaloids	Megalocytosis, fibrosis, biliary hyperplasia	Pulmonary and renal injury also occur.
<i>Senecio</i> spp.				
Leguminosae		Pyrrolizidine alkaloids	Megalocytosis, fibrosis, biliary hyperplasia	
<i>Crotalaria</i> spp.				
Boraginaceae		Pyrrolizidine alkaloids	Megalocytosis, fibrosis, biliary hyperplasia	
<i>Heliotropium</i> spp. <i>Echium</i> spp.				
Leguminosae	Cattle	Unknown	Centrilobular necrosis	Myocardial and skeletal muscle injury predominate in <i>Cassia occidentalis</i> intoxication.
<i>Cassia</i> spp.				
Zygophyllaceae	Sheep	Unknown	Crystalline material in bile ducts	Interaction with mycotoxin sporidesmin necessary to produce characteristic photosensitization (geeldikkop).
<i>Tribulus terrestris</i>				
Ulmaceae	Cattle, sheep, goats	Trematoxin	Centrilobular necrosis	Neuromuscular toxins also. Usually acute disease.
<i>Trema aspera</i>				
Solanaceae	Cattle, sheep	Saponins	Centrilobular necrosis	Gallbladder edema and hemorrhage. Usually acute disease.
<i>Cestrum parqui</i>				
Asteraceae	Sheep	Tetradymol	Centrilobular necrosis	Photosensitization is common.
<i>Tetradymia glabrata</i>				
Cycadales	Cattle, sheep, goats, dogs	Methylazoxymethanol	Centrilobular necrosis, megalocytosis, cholestasis	Toxin split from nontoxic glycoside. Neurotoxins also present. Chronic ingestion causes paralysis in cattle.
Zamiaceae				
Cycadaceae				
Stangeriaceae				

## Pathologic Basis of Veterinary Disease, 4th Edition

Fabaceae	Cattle, dogs	Indospicine	Centrilobular necrosis	Dogs can be intoxicated by eating meat from horses ingesting <i>Indigofera</i> .
<i>Indigofera</i>				
<i>linnaei</i>				
Cyanophyceae (Blue-green algae)	Cattle, sheep, horses, goats, dogs	Microcystins and others	Centrilobular to massive necrosis	Blue-green algae are not considered to be plants, but cyanobacteria. Multiple toxins are present. Can cause death by neuromuscular injury.
<i>Microcystis</i>				
<i>Aphanizomenon</i>

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Idiosyncratic drug reactions are characterized as responses seen in only a small minority of exposed individuals. There are a number of possible mechanisms for idiosyncratic drug reactions, including atypical metabolism as a result of inheritance of rare genes encoding enzymes involved in drug metabolism or deletions of genes encoding certain enzymes or immunologic responses to drugs or modified hepatocyte proteins. A list of selected idiosyncratic hepatotoxic drugs is listed in [Table 8-2](#). Interactions with other drugs or effects of diet and health status can also play a role. Diazepam toxicity in cats is an example of an idiosyncratic toxicity.

The response of the liver to acute hepatotoxic injury depends on the mechanism and site of toxic insult. By far, the most common pattern of acute liver toxicity is centrilobular necrosis. The mechanisms for this pattern of injury involve metabolism by the cytochrome p450 system and are discussed later. Certain chemicals that are uncommonly encountered these days produce periportal necrosis. These chemicals are able to produce a toxic effect without metabolism by the cytochrome p450 system and include phosphorus (once used as a rodenticide) and allyl alcohol.

It should be kept in mind that a single episode of nonlethal hepatotoxic injury in an otherwise healthy animal will be difficult to detect histologically within a few days after the episode. Within 48 to 72 hours, macrophages will clear cell debris, and hepatocytes will begin to undergo mitosis to replace the lost cells. Within a week or less, the liver regains a normal histologic appearance, unless there is massive necrosis, which can lead to collapse of the hepatic connective tissue scaffolding and subsequent fibrosis surrounding the central vein. Chronic toxic liver injury, manifest either as repeated bouts of toxin exposure or more consistent daily exposure (e.g., through dietary contamination) can lead to activation of hepatic stellate cells within the space of Disse or related myofibroblasts in the portal areas and the connective tissue of the central vein area, which may then initiate synthesis of extracellular matrix leading to hepatic fibrosis. In addition, chronic liver injury can lead to disruption of the normal framework that supports the hepatic architecture and leads to hepatic fibrosis. Sufficient injury also can produce nodules of regenerative hepatocytes that are surrounded by bands of fibrosis that connect central vein areas to each other, connect portal tracts to each other, or bridge portal tracts to centrilobular areas. This pattern is recognized as cirrhosis.

Hepatocytes are not the only cell type in the liver that can be affected by toxic drugs. The biliary epithelium (trimethoprim-sulfa, sporidesmin), Kupffer cells (endotoxin), endothelial cells (arsenicals), and the hepatic stellate cells (vitamin A excess) can all suffer chemically induced damage or, in the case of stellate cells, activation. Bile duct necrosis or proliferation can disrupt bile flow. Activated Kupffer cells can release cytokines that affect the type and degree of inflammation within the liver. Hepatic stellate cells play a central role in hepatic fibrosis as will be discussed later. Damage to endothelial cells can affect blood flow through the liver.

Hepatotoxic liver injury can be classified into six categories based on the cellular target involved:

1. The most frequent mechanism of hepatocellular injury involves production of injurious metabolites by the cytochrome p450 system. This family of enzymes is located in the smooth endoplasmic reticulum of hepatocytes primarily, although they are also found in many other cells of the body. A major role of cytochrome p450 enzymes is to metabolize lipid-soluble chemicals into water-soluble compounds for excretion from the body in bile or urine. In the first step of this three-step process, termed biotransformation, chemicals are bioactivated to a high-energy reactive intermediate molecule, termed phase I, in preparation for the second step, phase II, which involves formation of covalent bonds with polar molecules, such as glucuronic acid. This conjugation forms a water-soluble metabolite that can be excreted. Phase III involves the transport of these molecules across the cell membrane into the lumen of the canaliculus by molecular pumps.

442

443

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In some circumstances, such as an overdose, the high-energy reactive metabolites can form covalent bonds with other cellular constituents, such as proteins, and nucleic acids termed adducts. In acute toxicity, adducts with essential cellular enzymes may lead to cell injury or death. Toxic hepatocellular injury of this category occurs most often in the centrilobular area of the liver because this is the region of the liver with the highest concentration of cytochrome p450 enzymes. For instance, carbon tetrachloride is metabolized by cytochrome p450 enzymes to  $\text{CCl}_3\cdot$ , a free radical that is responsible for the toxicity of the parent compound. Lesions induced by carbon tetrachloride are most severe in the centrilobular (periacinar) areas, where the active form of the chemical is present in greatest concentration. Acetaminophen toxicity in dogs and cats and the many plant toxicities in herbivores are examples of injury produced by this mechanism.

2. Adduct formation between drugs and cellular enzymes, other proteins, or nucleic acids can alter the cellular constituents sufficiently that they become neoantigens, as may be the case with halothane toxicity. These neoantigens, like other foreign antigens, can be processed in the cytoplasm, transported to the cell surface, presented as antigens, and recognized by the immune system. Consequently the immune system may develop an inflammatory response toward hepatocytes or biliary epithelium that contain the adducts. Both cellular and humoral immunity can be involved. Injury can occur through direct cellular cytotoxicity and antibody-dependent cellular cytotoxicity. Although this mechanism is not well characterized in clinical veterinary medicine, it is likely to occur on occasion.
3. Certain toxins, including retained or excess hydrophobic bile acids, can trigger apoptosis (individual cell necrosis), by direct stimulation of proapoptotic pathways in the hepatocytes. Alternatively, apoptosis can be stimulated by immune-mediated events, such as those discussed previously, which lead to the release of tumor necrosis factor- $\alpha$  or activate Fas pathways.
4. Injury that damages cell membranes and disables enzymes responsible for calcium homeostasis, as seen in carbon tetrachloride toxicity, can lead to an influx of calcium. One consequence of the increased intracellular calcium is activation of proteases that damage actin filaments. Blebbing and lysis of the cell membranes can result.
5. Chemicals that bind to and disrupt the molecular pumps that secrete bile constituents into the canaliculi, such as estrogen and erythromycin, can produce cholestasis. More extensive hepatocellular injury that affects canalicular pumps and hepatocytes may produce cholestasis by disrupting the actin filaments situated around the bile canaliculi and preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts.
6. Hepatocyte injury or death can follow mitochondrial damage, as seen with some toxic antiviral nucleosides or intravenous tetracycline administration because the mitochondria are the powerhouse of the cell. Chemical or reactive oxygen species-induced injury to mitochondrial membranes, enzymes, or DNA can inhibit or disrupt mitochondrial function. Interference with mitochondrial  $\beta$ -oxidation of lipid leads to accumulation of free fatty acids and triglycerides producing a characteristic microvesicular steatosis. Disruption of the electron transport chain can release reactive oxygen species, which can produce widespread cellular damage. Also, damaged mitochondria do not produce sufficient adenosine triphosphate (ATP) to power the essential functions of the hepatocytes. In addition, release of cytochrome-c through damaged mitochondrial membranes can trigger apoptosis. Hepatocytic oxidative phosphorylation (ATP generation) and  $\beta$ -oxidation of lipids are reduced once the mitochondria are damaged, which leads to intrahepatic lipid accumulation (microvesicular steatosis), diminished energy production, and generation of reactive oxygen species, such as superoxide. Damaged mitochondria may

## Pathologic Basis of Veterinary Disease, 4th Edition

release cytochrome-c, triggering apoptosis, or if disruption of mitochondrial function is sufficient, hepatocyte necrosis ensues.

8.2.7.1

### HEPATOTOXIC AGENTS

8.2.7.1.1

#### Blue-Green Algae

Blue-green algae are now classified in the phylum Monera, division Cyanophyta; are considered to be more closely related to bacteria; and are no longer considered members of the plant family. Several genera of blue-green algae, including *Anabaena*, *Aphanizomenon*, and *Microcystis*, can cause lethal poisoning of livestock and less commonly small animals, such as dogs and cats. Algal blooms usually occur in late summer or early fall because of the warm temperatures, long hours of sunlight, and abundance of essential nutrients. Dead and dying algae, which contain preformed toxins, such as microcystin LR, a cyclic heptapeptide, accumulate on the surface of bodies of water and are ingested by livestock. Secondary bacterial growth in dying algae may contribute to toxin formation. Signs develop rapidly and include diarrhea, prostration, and death. Gross lesions include hemorrhagic gastroenteritis and a red, swollen, hemorrhagic liver. Histologically, zonal, or even massive, hepatic necrosis and hemorrhage is evident. Animals that survive the acute manifestations may develop clinical signs of chronic liver disease. Other preformed toxins that affect different organ systems, including the nervous system, have also been identified in blue-green algae.

443

444

8.2.7.1.2

#### Toxic Plants

Toxic plants of great variety cause hepatic injury in domestic animals. A comprehensive discussion of each is beyond the scope of this chapter. The phytotoxins (Table 8-1) to be discussed represent two distinct types. The first of these, represented by pyrrolizidine alkaloids, must be metabolized to an active form in the liver. The second type of toxin is deconjugated by bacteria within the digestive tract to release a factor that is subsequently bioactivated in the liver.

Pyrrolizidine alkaloids are found in many plant families, including Compositae, Leguminosae, and Boraginaceae, that occur throughout much of the world. The most important genera are *Senecio*, *Cynoglossum*, *Amsinckia*, *Crotalaria*, *Echium*, *Trichodesma*, and *Heliotropium*. Approximately 100 different alkaloids are recognized; toxic effects depend upon which alkaloids are present within ingested plants. Ingested alkaloids are converted to pyrrolic esters by hepatic cytochrome p450 enzymes. These esters are alkylating agents, which react with cytosolic and nuclear proteins and nucleic acids. Pigs are particularly susceptible to pyrrolizidine alkaloid intoxication, sheep considerably less so, and cattle and horses are intermediate in susceptibility. Most cases of intoxication arise from chronic intoxication and the gross lesion is typically hepatic fibrosis (Fig. 8-73, A). The characteristic histologic lesions of pyrrolizidine alkaloid intoxication are the megalocytes, which are hepatocytes with enlarged nuclei and increased cytoplasmic volume. Megalocytes may be many times the size of normal hepatocytes (Fig. 8-73, B). Megalocytes are the result of the antimitotic effects of pyrrolizidine alkaloids, which prevent cell division but not DNA synthesis because the hepatocytes attempt to divide to replace those that have undergone necrosis. This change, although indicative of pyrrolizidine alkaloid intoxication, is not pathognomonic, because it occurs with other toxins, such as aflatoxins and nitrosamines. Typically, chronic pyrrolizidine intoxication is accompanied by hepatic fibrosis, biliary proliferation, and in some circumstances nodular regeneration of parenchyma. Nodular regeneration does not always occur because hepatocyte proliferation can be inhibited by pyrrolizidines; however, exposure is not likely to be constant, and there may be periods during which hepatocyte replication can occur, such as the end of the dry season

## Pathologic Basis of Veterinary Disease, 4th Edition

when more desirable plant species reappear. Species differences may also have an effect on the hepatic response to pyrrolizidines because cattle have regenerative nodules more often than horses. Chronic hepatic damage can lead to hepatic failure and its associated constellation of signs (described in detail earlier).

**Fig. 8-73 Chronic pyrrolizidine hepatotoxicity, cow.** **A**, Chronic pyrrolizidine intoxication produces a fibrotic and sometimes distorted liver with an irregular capsular surface. **B**, Greatly enlarged hepatocytes (megalocytes) in the persisting parenchyma are typical of pyrrolizidine toxicity. H&E stain. (**A** and **B**, Courtesy Dr. P. Carbonell, School of Veterinary Science, Melbourne.)

Cycads are primitive palmlike plants that inhabit tropical and subtropical regions. They contain cycasin, a nontoxic glycoside, which following ingestion is deconjugated by intestinal bacteria to release a toxic metabolite, methylazoxymethanol. Following absorption into the portal vein, hepatic metabolism of this compound yields alkylating agents, leading to acute or chronic liver injury. Chronic hepatic lesions in cattle include hepatocellular megalocytosis caused by the mitoinhibitory effects of alkylating agents and nuclear hyperchromasia, and varying degrees of hepatic fibrosis. Chronic cycad poisoning in cattle causes a nervous disease with progressive proprioceptive deficits in the hind legs because of “dying back” of axons in the dorsal funiculus and the spinocerebellar and corticospinal tracts. Acute intoxication is more common in sheep than in other species and produces acute gastrointestinal dysfunction and centrilobular hepatic necrosis. Dogs can also be intoxicated by cycads.

444

445

### 8.2.7.1.3

#### Mycotoxins

Mycotoxins are secondary metabolites of fungi; that is, their production is not necessary for the survival of the fungus. The amount of toxin synthesized by a given strain of fungus reflects the genetic constitution of the particular strain, presence of appropriate substrate, temperature, humidity, and available nutrients. There are several hepatotoxic mycotoxins of veterinary significance.

### 8.2.7.1.4

#### Aflatoxin

Aflatoxins are produced by the fungus *Aspergillus flavus*. Aflatoxin B<sub>1</sub> is the most common form and is also the most potent toxin and carcinogen. Aflatoxins are usually elaborated during storage of fungus-contaminated feed, particularly in humid conditions, and may be present in many crops, including corn, peanuts, and cottonseed. Aflatoxins are converted to toxic intermediates by hepatic cytochrome p450 enzymes. Carcinogenic, toxic, and teratogenic effects of aflatoxins reflect binding of the toxic intermediates to cellular DNA, RNA, or proteins. Pigs, dogs, horses, cattle and ducks, especially younger animals, are sensitive to the toxic effects of aflatoxins, whereas sheep are more resistant. Acute aflatoxin intoxication is rare in horses and cattle because an inordinately large amount of contaminated feed would have to be ingested to achieve a sufficient dose. Acute aflatoxicosis in dogs is characterized by hemorrhagic central to massive necrosis. Lipidosis and biliary proliferation also may occur. Chronic intoxication is more common than acute intoxication and results in ill-thrift, increased susceptibility to infection, and occasionally signs of hepatic failure. Affected livers are firm and pale and microscopically are characterized by lipidosis and necrosis of hepatocytes, biliary hyperplasia, centrilobular to bridging fibrosis, and cellular atypia of hepatocytes, characterized by variable cells size and variable nuclear size (Fig. 8-74, A and B).

Fig. 8-74 **Chronic hepatic aflatoxicosis.** **A**, Postnecrotic scarring, pig. Chronic aflatoxicosis produces a shrunken and fibrotic liver from collapse of areas of massive necrosis and condensation of the fibrous stroma. **B**, Histologic appearance. Chronic aflatoxicosis is characterized by variable amounts of fatty change, biliary hyperplasia, and cellular atypia in hepatocytes. H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

8.2.7.1.5

### Sporidesmin

The mycotoxin sporidesmin is produced by *Pithomyces chartarum*, a fungus that grows particularly well in dead rye grass (*Lolium perenne*), a common pasture plant in New Zealand and Australia. Ingestion of sufficient amounts of the toxin produces necrosis of the epithelium of large intrahepatic and extrahepatic biliary ducts in sheep and less so in cattle. Cholestasis with a concurrent failure to excrete phyloerythrin frequently leads to photosensitization with skin lesions predominantly on the head, thus the common name facial eczema. Acute cases are characterized by a bile-stained liver with prominent small-caliber bile ducts. These are dilated by bile in the lumens and surrounded by periductal edema. In chronic cases of facial eczema, the bile ducts become thickened by fibrosis secondary to biliary epithelial necrosis and subsequent inflammation (chronic cholangitis). Perhaps because of streaming of blood in the portal vein, the left lobe of the liver (although this lobe occupies the ventral portion of the ruminant liver), which may have an increased proportion of blood draining from the small intestine, is usually most severely affected and in severe cases undergoes atrophy and fibrosis.

445

446

A similar disease, Geeldikkop, which is characterized by hepatogenous photosensitization, occurs in sheep in South Africa that ingest puncture vine (*Tribulus terrestris*). It was previously thought to be caused by a mycotoxin, but recent studies have revealed that it is caused by ingestion of steroidal sapogenins that can damage or obstruct the bile ducts.

8.2.7.1.6

### Phomopsins

Phomopsins are toxic metabolites of the fungus *Phomopsis leptostromiformis*. The fungus grows on lupine (*Lupinus* sp.), and cattle, sheep, and occasionally horses that graze contaminated lupine stubble develop hepatic injury. Hepatic dysfunction is usually chronic, and the liver is atrophic and fibrotic. The microscopic appearance of affected livers is characterized by diffuse scattered hepatocyte necrosis with a background of mitotic figures, often appearing to be arrested in metaphase. Later in the course of the disease, diffuse fibrosis and biliary hyperplasia predominate. Signs of hepatic failure, including photosensitization, may occur in affected animals. This mycotoxicosis should not be confused with the condition known as lupinosis, which is caused by naturally occurring alkaloids in lupines that are capable of inducing skeletal deformities, but not obvious hepatic injury.

8.2.7.1.7

### Mushrooms

Poisonous mushrooms, such as *Amanita* species and others, can cause acute fatal liver necrosis. Intoxication by *Amanita phalloides*, known as the death cap, is caused by a group of toxins termed toxic cyclopeptides. This species is particularly toxic; a single gram of this mushroom is sufficient to kill a human, and even smaller amounts are likely to prove fatal to dogs. Amatoxin, an octapeptide, is in particular responsible for hepatocellular injury. The mechanism of injury is attributed to inhibition of RNA polymerase II function disrupting DNA and RNA transcription. Gross lesions usually consist of hepatic hemorrhage and a shrunken liver because of the loss of hepatocytes. Hepatocellular lipidosis, hemorrhage, and centrilobular to massive necrosis are the typical lesions. Death from liver failure may occur 3 to 4 days after the onset of clinical signs. Phalloidin, a toxic heptapeptide found in *Amanita* species, causes disruption of intracellular actin filaments, leading to cell injury or death. It is a less significant toxin in natural exposure because of the limited absorption from the digestive tract. Other mushroom species contain different toxic agents.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.7.2 HEPATOTOXIC CHEMICALS

#### 8.2.7.2.1 Phosphorus

Phosphorus occurs in two forms: red phosphorus and white phosphorus. Red phosphorus is unimportant as a toxin, but white phosphorus was previously used as a rodenticide. The mechanism of phosphorus toxicity is unclear, although it apparently is directly toxic. Poisoning is first indicated by signs of gastroenteritis and subsequently by microscopic lesions of lipidosis of hepatocytes and periportal necrosis. The pattern of periportal necrosis is unusual because most toxic liver injury occurs in the centrilobular region of the liver. This is explained by the fact that white phosphorus does not require metabolic transformation to a reactive intermediate by cytochrome p450 enzymes, which are most concentrated in the centrilobular region of the liver lobule.

#### 8.2.7.2.2 Carbon Tetrachloride

Carbon tetrachloride is the classic example of a hepatotoxin that must be bioactivated by the mixed-function oxidase system to produce a toxic intermediate form. Although once used widely, it is only occasionally used as an anthelmintic. Carbon tetrachloride produces centrilobular hepatic necrosis and lipidosis of surviving hepatocytes (see [Chapter 1](#)).

#### 8.2.7.2.3 Cresols

Cresols once were incorporated in clay pigeons and asphalt shingles. If pigs ingest cresols, centrilobular to massive hepatic hemorrhage and necrosis result, a pattern that can also be seen in pigs with hepatitis dietetica or in those that ingest cotton seed meal.

#### 8.2.7.2.4 Metals

Several metals can cause toxic hepatic injury. Copper toxicity may present as an acute intravascular hemolytic anemia in ruminants or as chronic hepatic injury and end-stage hepatic disease in dogs. Excessive iron supplementation in dogs and cats may result in excessive storage of iron and subsequently hepatic disease caused by iron overload, termed hemochromatosis. Two specific syndromes of iron poisoning are iron-dextran intoxication of piglets and ferrous fumarate (a component of a specific dietary supplement) intoxication of newborn foals. Severe cases of these two toxicities are characterized by massive hepatic necrosis. Intoxication of foals with ferrous fumarate occurred following its use as a component of a specific dietary supplement, and was characterized by massive necrosis and also a remarkable amount of hyperplasia of bile ducts and cholangioles, possibly with oval cell proliferation, despite the short clinical course of the disease. Iron-dextran is frequently administered intramuscularly to suckling pigs to prevent anemia, but administration of iron-dextran has occasionally resulted in significant mortality, and affected pigs die soon after injection.

446

447

### 8.2.7.3 HEPATOTOXIC THERAPEUTIC DRUGS

There are a variety of drugs that have a proven therapeutic application, but can cause significant acute or chronic hepatic injury in some animals. Clearly, these drugs would not be used if the proportion of injured animals was high, but it is important to keep in mind that many drugs have the potential to cause hepatic

## Pathologic Basis of Veterinary Disease, 4th Edition

injury in some patients. The mechanisms by which these drugs cause injury vary by species and by individual. Some therapeutic drugs are predictable toxins, and all members of a particular species are susceptible to liver injury if a sufficient dose is given. But because the therapeutic effect occurs at a lower dose than the toxic dose, liver injury occurs only when overdoses are ingested. Hepatic metabolism (bioactivation) of these compounds is likely to be involved because the site of liver injury is typically centrilobular. Cats are more susceptible than dogs to intoxication by many chemicals because they are relatively deficient in hepatic glucuronyltransferase activity. This phase II enzyme forms conjugates between bioactivated (phase I) xenobiotics and glutathione. When phase II metabolism is overwhelmed, injurious bioactivated products cause liver injury. Cats are more sensitive to acetaminophen intoxication than dogs because of this relative enzyme deficiency. Other therapeutic drugs are idiosyncratic toxins, and they affect only a small minority of patients. The mechanism of injury is not known but may be a consequence of inherited differences in hepatic enzyme content and activity, or atypical immune reactions to drug metabolites, or novel antigens created when drug metabolites bind to cellular proteins may play a role. For example, the antiinflammatory drug carprofen can occasionally cause acute hepatic necrosis in a variety of dogs, but certain breeds of dogs, such as Labrador retrievers, are affected more often than others. The tranquilizer diazepam can cause acute fatal hepatic injury in some cats, but the majority of treated cats are unaffected, and dogs do not seem to be adversely affected.

Chronic liver toxicity has been described in dogs receiving any of the anticonvulsants, primidone, phenytoin, and phenobarbital for prolonged periods. The mechanism of hepatotoxicity is unknown. Only a small proportion of dogs receiving these drugs are affected, and these dogs frequently have signs of hepatic failure. The liver is small and has widespread hepatic fibrosis and nodular regeneration (end-stage liver).

### 8.2.8 DISEASES OF UNCERTAIN CAUSE

#### 8.2.8.1 EQUINE SERUM HEPATITIS

This disease was first described by Theiler in South Africa at the beginning of the twentieth century, but now is recognized in many countries. It occurs frequently, but not invariably, in horses that have received an injection of a biologic that contains equine serum; for instance, equine antisera, such as tetanus antitoxin or pregnant mare serum gonadotropin. It appears that an infectious agent is responsible, although none has been identified. The incubation period is prolonged, but the clinical course of the disease is very rapid and is invariably fatal. Affected horses typically have hepatic failure, which manifests as hepatic encephalopathy and icterus. Intravascular hemolysis occurs in the terminal stages of the disease. The livers of affected animals are typically small, flabby, and discolored greenish brown to dark brown (Fig. 8-75, A). The liver of affected animals is small and friable, with an enhanced lobular pattern because of diffuse centrilobular degeneration and necrosis of hepatocytes and subsequent congestion of these necrotic areas (Fig. 8-75, B). Frequently, only narrow rims of hepatocytes around portal areas (periportal hepatocytes) survive, and these sometimes are accompanied by proliferating tubules or columns of cells, which are speculated to have arisen from the cholangioles and probably are a regenerative response.

#### 8.2.8.2 CANINE CHRONIC HEPATITIS (CHRONIC-ACTIVE HEPATITIS)

Chronic hepatitis in dogs is a poorly understood, in most cases, persistent inflammation of the liver. The terminology of this entity, in keeping with the inflammatory process, has been a persistent topic of dispute. Chronic-active hepatitis is a descriptive term that has been used to identify a particular pattern of inflammation in the human liver. Originally the purpose of this classification was to identify hepatic lesions, regardless of cause, that were predictive of a progressive course of inflammation and fibrosis. This term was

## Pathologic Basis of Veterinary Disease, 4th Edition

adopted by veterinary pathologists and used to indicate hepatic disorders of the dog that have microscopic changes similar to those seen in human livers. Based on usage, the term *chronic active hepatitis* has incorrectly evolved from a morphologic description into a disease entity. The appropriateness and usefulness of this designation is conjectural in human beings and in dogs. Recent publications in the medical literature have argued that this terminology should be abandoned because it is no longer regarded as useful in predicting the course of liver disease, and it ignored the cause of the liver inflammation. Accordingly the term chronic hepatitis is preferred to describe this entity in dogs.

447

448

**Fig. 8-75 Equine serum hepatitis, liver, horse. A,** Livers from horses affected with equine serum hepatitis can be small, flabby and pale or discolored by bile pigment. **B,** In horses with equine serum hepatitis, most hepatocytes are necrotic, although there may be a few remaining hepatocytes with lipid-containing vacuoles in the periportal regions (*P*). Inflammation consists of mononuclear cells predominantly. H&E stain. (**A**, Courtesy Dr. K. Bailey, College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

The term *chronic hepatitis*, with modifiers indicating the type and degree of inflammation and fibrosis, is used to fully characterize the activity and stage of the lesion. If the cause of the inflammation is known, it should be included in the diagnosis. The cause of most of the spontaneous cases of canine chronic (chronic-active) hepatitis is undetermined, although some cases have been hypothesized to be caused by leptospira infection or experimental canine adenovirus I infection. Progressive chronic hepatitis has been described in cases of hereditary copper toxicosis of Dalmatians and Bedlington and West Highland white terriers and was described earlier under Metabolic Disturbances and Hepatic Accumulations. Familial chronic hepatitis also is usually characterized by excessive hepatic accumulation of copper in the Doberman pinscher (females are predisposed), Skye terrier, cocker spaniel, and Labrador retriever. Although abnormal concentrations of hepatic copper in at least some of these breeds have been attributed to cholestasis and decreased excretion of copper in bile, the actual mechanism of copper retention remains unclear. Many dogs with chronic hepatitis do not have elevated liver concentrations of hepatic copper, and a wide range of hepatic copper concentrations is present in clinically normal dogs. Thus the precise role of copper in mediating chronic hepatic disease in breeds of dogs other than the Bedlington terrier and Dalmatian remains uncertain.

The liver in cases of chronic hepatitis is usually small, often with an accentuated lobular pattern; severely affected livers are characterized by architectural distortion, which ranges from a coarsely nodular texture to an end-stage liver (Fig. 8-76, A). Chronic hepatitis, depending on the duration of inflammation and injury, is characterized by portal and periportal mononuclear cell inflammation, intrahepatic cholestasis, and fibrosis of portal areas that may extend into adjacent periportal areas of the lobule, leading to the prominent lobular pattern (Fig. 8-76, B).

### 8.2.9

#### HEPATIC INJURY AS A CONSEQUENCE OF SYSTEMIC DISEASE

A variety of extrahepatic disorders, usually affecting the gastrointestinal tract, can result in hepatocellular injury and hepatic dysfunction. Acute hemorrhagic pancreatitis of dogs, for example, sometimes is accompanied by icterus and increased activities of hepatic enzymes in serum. Release of various toxins and inflammatory mediators from the injured pancreas into the portal vein showers the liver with a variety of injurious substances. Similarly, movement of hepatotoxic substances, such as endotoxins, into the portal vein can occur as a consequence of diseases that disrupt the mucosal barrier of the intestine. Some cases of chronic inflammation of the colon can result in chronic hepatic inflammation as well. Accumulation of inflammatory cells within the portal triads may accompany blood-borne infection or abdominal sepsis (nonspecific reactive hepatitis).

The liver is particularly susceptible to the effects of hypoxia; thus any disease that causes anemia can produce centrilobular or paracentral degeneration and necrosis. Also, the hepatocytes in hemolytic anemias must remove and conjugate the increased amounts of circulating bilirubin and hemoglobin, and Kupffer cells must remove either erythrocytes during extravascular hemolysis or erythrocytic fragments during intravascular hemolysis.

448

Fig. 8-76 **Chronic active hepatitis.** **A**, Liver, diaphragmatic surface, dog. The liver is characterized by scattered regenerative nodules of different sizes and extensive fibrosis that gives the liver an irregular surface. **B**, End-stage liver with chronic hepatitis. The liver lobular architecture is replaced by irregular nodules of regenerative parenchyma separated by tracts of connective tissue with an inflammatory infiltrate and pigment accumulation. ## Pathologic Basis of Veterinary Disease, 4th Edition

### 8.2.10 PROLIFERATIVE LESIONS OF THE LIVER

#### 8.2.10.1 HEPATOCELLULAR NODULAR HYPERPLASIA

Hepatocellular nodular hyperplasia is common only in the dog. The incidence increases with age, starting around 6 years of age, without predilection for either sex or breed. Nodular hyperplasia is not the result or the cause of significant hepatic dysfunction, but nodular hyperplasia should be distinguished from regenerative nodules and hepatic neoplasms, with which they are often confused. Multiple hyperplastic nodules are frequently present. Nodules that can be seen on the capsular surface are typically raised and hemispherical, yellow to tan (although they can be dark red when congested), 0.5 to 3 cm in diameter, and are more friable than normal liver. On incision, the hyperplastic nodules are well demarcated from normal parenchyma and usually compress adjacent parenchyma (Fig. 8-77, A and B). Hyperplastic nodules contain all the elements of normal liver, but the lobular pattern is distorted. The lobules in areas of nodular hyperplasia contain an increased proportion of hepatocytes and decreased numbers of portal tracts and central veins compared with a normal liver. Hepatocytes are variably sized and frequently contain cytoplasmic lipid or glycogen-containing vacuoles (Fig. 8-77, C).

#### 8.2.10.2 REGENERATIVE NODULES

Regenerative nodules are another type of nodular hepatocellular lesion. Regenerative nodules are unlikely to be related to nodular hyperplasia, because regenerative nodules arise from the proliferation of hepatocytes in response to loss of hepatocytes, and the incidence is not related to age. Often the insult is unknown, but the response of some dogs to anticonvulsant drugs, such as phenobarbital or phenytoin, is a well-recognized cause. Regenerative nodules are readily distinguished from nodular hyperplasia because the process occurs in the presence of significant fibrosis and disruption of normal hepatic parenchymal architecture. Because these lesions result from the outgrowth of surviving hepatocytes, there is usually only a single portal tract apparent in sections of the regenerative nodules.

#### 8.2.10.3 CHOLANGIOCELLULAR (BILE DUCT) HYPERPLASIA

Hyperplasia of biliary ductules commonly occurs as a nonspecific response to a variety of hepatic injuries and has been described under Response of the Liver to Injury. Reactive proliferation of the bile ductules of the liver must be distinguished from neoplastic proliferations.

#### 8.2.10.4 HEPATIC NEOPLASIA

Primary neoplasms of the hepatobiliary system can arise from epithelial elements, including hepatocytes, biliary epithelium of bile ducts or the gallbladder, and mesenchymal elements, such as connective tissue and blood vessels. The liver is a common site of metastasis for many malignant tumors; in fact, the majority of neoplasms within the liver are metastases from other organs.

##### 8.2.10.4.1 Hepatocellular Adenoma

Hepatocellular adenomas are benign neoplasms of hepatocytes. Hepatocellular adenomas have been described most commonly in young ruminants. The neoplasms usually are single, unencapsulated, variably sized, red or brown masses that compress adjacent parenchyma. They are typically spherical, but

449

450

## Pathologic Basis of Veterinary Disease, 4th Edition

may be pedunculated (Fig. 8-78). They are composed of well-differentiated hepatocytes, which form uniform plates that may be two to three cells thick. Hepatic plates in adenomas tend to abut normal adjacent hepatocytes at right angles. Portal tracts and central veins are scarce within the neoplasm, if they can be found at all. Diagnostic criteria to distinguish hepatocellular adenomas from hepatocellular nodular hyperplasia can be somewhat subjective because both arise in livers with no background abnormality, unlike regenerative nodules that arise in damaged livers. Histologically, adenomas are characterized by only one or very few portal tracts, whereas hyperplastic nodules retain normal lobular architecture elements, although the portal tracts are more separated than normal. In other cases, it may be difficult to distinguish hepatocellular adenomas from well-differentiated hepatocellular carcinomas.

**Fig. 8-77 Hepatic nodular hyperplasia, Liver, dog.** **A**, A nodule protrudes above the surface of the adjacent, normal parenchyma. **B**, Nodular hyperplasia, cut surface of liver. Two hyperplastic nodules are shown. **C**, A hyperplastic nodule compresses adjacent hepatocytes, and the hepatocytes of the nodule can be prominently vacuolated as in this case. H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. R. Fairley, Lincoln University. **C**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

**Fig. 8-78 Hepatocellular adenomas, liver, dog.** Hepatocellular adenomas form discrete masses of hepatocytes that compress adjacent normal parenchyma. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

8.2.10.4.2

### Hepatocellular Carcinoma

Hepatocellular carcinomas are malignant neoplasms of hepatocytes. They are uncommon in all domestic species but may occur more frequently in ruminants, particularly sheep. These neoplasms are often solitary, frequently involve an entire lobe, and are well demarcated. They typically consist of friable, gray-white or yellow-brown tissue, which is subdivided into lobules by multiple fibrous bands (Fig. 8-79, A). Malignant hepatocytes characteristically form irregular plates (trabeculae) three or more cells thick, and vascular spaces are present between the trabeculae (Fig. 8-79, B). Crude acini forming a pseudoglandular pattern of neoplastic cells are sometimes present. Within an individual tumor, trabecular, pseudoglandular, and solid patterns may be found. Cells present in the neoplasm range from well-differentiated hepatocytes to atypical or bizarre forms. In the absence of metastasis, which is obviously indicative of malignancy, distinction of well-differentiated carcinoma from adenoma can be difficult, although invasion by malignant hepatocytes at the margin of the adjacent compressed normal hepatocytes and hepatocellular atypia are useful indicators of malignancy. Metastasis to a variety of sites may occur, particularly to lymph nodes within the cranial abdomen, lungs, and seeding into the tissue of the peritoneal cavity. Some hepatocellular carcinomas extensively spread within the liver (intrahepatic metastasis).

450

451

Fig. 8-79 **Hepatocellular carcinoma, liver, dog.** **A**, A multilobular carcinoma has replaced much of the normal liver. **B**, Hepatocellular carcinomas contain pleomorphic hepatocytes that can form trabeculae, a glandular-like pattern or solid sheets of cells, as in this case. H&E stain. (**A**, Courtesy College of Veterinary Medicine, North Carolina State University. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

### 8.2.10.4.3

#### Cholangiocellular (Bile Duct) Adenoma

Adenomas of the biliary ducts are uncommon in most species but may be the most common primary hepatic neoplasm in cats. They are usually discrete, firm, gray or white masses consisting of

## Pathologic Basis of Veterinary Disease, 4th Edition

---

well-differentiated biliary epithelium. Cholangiomas are glandlike structures formed by tubules lined with cuboidal epithelium and moderate amounts of stroma. The tubules may have narrow lumens or may be distended by fluid-forming cystic structures of variable sizes. Cystic variants, biliary cystadenomas, typically have a nonencapsulated, multilocular cystic structure. Hepatocytes are usually compressed at the margins or may on occasion be entrapped by expanding cysts. The stroma of the cyst wall consists of fibrovascular tissue with moderate amounts of collagen. Cysts are lined with benign biliary epithelium (simple cuboidal to flattened). The lining epithelium tends to be more flattened in the biliary cystadenomas, presumably because of compression. Biliary epithelial cells may form papillary projections extending into the cystic spaces.

In cats, large cystic cavities that are lined with flattened biliary epithelium are regarded as adenomas or cystadenomas by some investigators, but it may be more appropriate to consider them to be congenital malformations. Congenital biliary cysts are multiloculated and can involve extensive areas of the liver. Typically, they have flattened epithelium and varying amounts of fibrous tissue, and islands of hepatocytes are often scattered between the cysts.

8.2.10.4.4

### Cholangiocellular (Bile Duct) Carcinoma

Cholangiocellular carcinomas are malignant neoplasms of biliary epithelium, which usually arise from the intrahepatic ducts, but extrahepatic bile ducts can be affected. These neoplasms occur in all species. A large single mass or multiple nodules may be present within the liver; these typically are firm, raised, often with a central depression (umbilicated), pale gray to tan, and unencapsulated (Fig. 8-80, A). The tumors are composed of cells that retain a resemblance to biliary epithelium. Characteristically, well-differentiated carcinomas are organized into a tubular or acinar arrangement. In less differentiated neoplasms, some acinar arrangements can be detected among solid masses of neoplastic cells. Poorly differentiated carcinomas are composed of packets, islands, or cords, and areas of squamous differentiation can occur. The epithelial components of the neoplasms are usually separated by fibrous connective tissue (Fig. 8-80, B). The amount of connective tissue varies among tumors, but an abundant deposition of collagen, termed a scirrhous response, is relatively common and is responsible for the firm texture of these neoplasms. The margins of cholangiocarcinomas are characterized by multiple sites of local invasion by tumor cells of surrounding hepatic parenchyma. Multiple sites of hepatic necrosis are also common in the adjacent parenchyma.

451

452

Fig. 8-80 **Cholangiocellular carcinoma, liver.** **A**, Dog. Multiple nodules of tumor, some of which are umbilicated (*arrows*). **B**, Cat. Cords and acini of neoplastic bile duct epithelial cells (*N*) are invading the adjacent normal hepatic parenchyma (*H*). H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. J. Simon, College of Veterinary Medicine, University of Illinois.)

Metastasis to extrahepatic sites is common, particularly to the adjacent lymph nodes of the cranial abdomen, lungs, or by seeding into the abdominal cavity. Metastasis into the peritoneal cavity can produce variably sized nodules within the mesentery and on the serosal surface of the abdominal viscera.

## Pathologic Basis of Veterinary Disease, 4th Edition

8.2.10.4.5

### Carcinoids

Carcinoids are uncommon tumors that are believed to arise from neuroendocrine cells that lie within the biliary epithelium. They can form within the intrahepatic or extrahepatic biliary system. Often they form a single mass, but multiple nodules can occur, probably secondary to intrahepatic metastasis. Cells tend to be small, elongated, or spindle-shaped and form ribbons or rosettes (Fig. 8-81). Immunohistochemical detection of neuroendocrine markers, such as chromogranin A, can be used to confirm the diagnosis.

8.2.10.4.6

### Miscellaneous Primary Mesenchymal Neoplasms of the Liver

Primary neoplasms can arise from any of the cellular constituents of the liver, including mesenchymal neoplasms derived from the liver's connective tissue (fibrosarcoma, leiomyosarcoma, and osteosarcoma) and endothelium (hemangioma and hemangiosarcoma). Primary hepatic hemangiosarcoma is well recognized in dogs, although it is a relatively uncommon site of origin for this neoplasm as compared with the skin and spleen. Primary mesenchymal neoplasms of the liver must be distinguished from metastases; the presence of disseminated masses throughout the liver is more typical of metastatic sarcomas than of primary hepatic sarcomas.

8.2.10.4.7

### Metastatic Neoplasms

The liver and the lung are the two most common sites for metastatic spread of malignant neoplasms. Metastatic neoplasms must be distinguished from primary hyperplasia or neoplasia of the hepatobiliary tissue. It is important, therefore, when evaluating a neoplasm within the liver to determine if a neoplasm is present at some extrahepatic site that might be the primary neoplasm. The animal's medical history should also be reviewed to determine if masses have been removed previously. Malignant lymphoma is the most common metastatic neoplasm found in the liver of most, if not all, species.

452

453

**Fig. 8-81 Neuroendocrine tumors, carcinoid, liver, dog.** Carcinoids are malignant neoplasms of neuroendocrine cells of the liver or bile ducts. Histologically the tumor is composed of small elongated or spindle-shaped basophilic cells that form ribbons or rosettes and contain numerous vascular spaces. H&E stain. (Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Some metastatic neoplasms have a typical appearance within the liver; for example, melanomas frequently are black because of the presence of melanin, and hemangiosarcomas are usually dark red to brown because of blood. Hematopoietic neoplasms, such as lymphoma and the myeloproliferative disorders, can diffusely expand the liver and can have diffuse infiltrative (Fig. 8-82, A) and nodular (Fig. 8-82, B) variants, thus producing hepatomegaly and an enhanced lobular pattern on the cut surface, or they may have a nodular appearance. This characteristic appearance of diffuse involvement is attributable to centrilobular hepatocellular degeneration because of anemia in both lymphoma and myeloproliferative disorders and because of the specific location of accumulations of neoplastic cells; locations include portal and periportal for lymphomas (Fig. 8-82, C) and sinusoidal for myeloproliferative disorders. Metastatic carcinomas often have an umbilicated appearance, similar to that seen with cholangiocellular carcinomas, but umbilication is rarely a feature of sarcomas.

### 8.2.11 DISEASES OF THE GALLBLADDER

#### 8.2.11.1 CHOLELITHIASIS

Choleliths, or gallstones as they are commonly called, occur infrequently in all the domestic species, but they are especially well described in ruminants. Choleliths are concretions of normally soluble components of bile (Fig. 8-83). They form when these components become supersaturated and precipitate. Choleliths in the gallbladder usually do not become clinically significant unless they migrate and obstruct the extrahepatic bile ducts.

#### 8.2.11.2 CHOLECYSTITIS

Cholecystitis is inflammation of the gallbladder and can be acute or chronic. Acute inflammation of the gallbladder may be produced by viral infections, such as Rift Valley fever in ruminants and infectious canine hepatitis and produces characteristic edema and hemorrhage in the gallbladder. Fibrinous cholecystitis may occur in calves with acute salmonellosis, particularly that caused by *Salmonella enteritidis* serotype *dublin* (Fig. 8-84). Other bacteria, either derived from the blood or ascended from the intestine, can cause acute or chronic cholecystitis. Chronic cholecystitis typically accompanies prolonged bacterial infection of the biliary tree, or ongoing irritation from choleliths or parasites of the gallbladder. Rupture of the gallbladder is rare but can occur as a result of acute or chronic infection. The resultant release of bile, with or without accompanying bacteria, can cause life-threatening peritonitis because of the irritating effect of bile on the serosal surfaces of the abdomen.

**Fig. 8-82 Hepatic lymphoma (lymphosarcoma), liver.** **A**, Cut surface, high magnification, dog. The entire liver is enlarged (not shown here), and there are multiple pale foci caused by infiltrating neoplastic lymphocytes. The regular distribution of neoplastic foci apparent on the cut surface is due to the preferential infiltration of the portal tracts by neoplastic cells. **B**, Cow. As shown here, hepatic lymphoma can have a nodular rather than a diffuse pattern, as seen in [Fig. 8-82, A](#). **C**, dog. Neoplastic lymphocytes are typically distributed within and around the portal tracts and central veins ([Fig. 8-82, A](#)). H&E stain. (**A** and **C**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

(Courtesy Dr. D.A. Mosier, College of Veterinary Medicine, Kansas State University.)

### 8.2.11.3 THROMBOSIS AND INFARCTION OF THE GALLBLADDER

Occasionally, infarction without significant inflammation of the gallbladder can be seen in dogs. Thrombi can be found in the arteries of the muscular wall of the affected gallbladders. Rupture of the gallbladder can occur secondarily to the infarction of the wall. The cause is not known.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.11.4 GALLBLADDER MUCOCELE

Gallbladder mucocele refers to a syndrome in dogs characterized by a distended gallbladder filled with mucus that is often associated with signs of biliary obstruction and that can occasionally lead to gallbladder rupture. Small breed dogs appear to be most often affected. The mucosa of the gallbladder is usually hyperplastic. Occasionally the common bile duct is similarly affected and cholestasis can develop.

### 8.2.11.5 HYPERPLASTIC AND NEOPLASTIC LESIONS

#### 8.2.11.5.1 Cystic Mucinous Hyperplasia of the Gallbladder

Cystic mucinous hyperplasia of the gallbladder mucosa has only been reported in dogs and sheep. There are no apparent abnormalities evident from the exterior of the gallbladder, and the features of cystic hyperplasia can only be appreciated by opening the gallbladder and draining residual bile that may obscure the mucosa. When the bile is rinsed away, affected mucosa is gray-white and has a diffusely thickened, spongelike consistency. Sessile or polypoid masses are occasionally found and occasionally large cysts occur, and they are evident as papillary projections into the lumen of the gallbladder (Fig. 8-85). Numerous 1- to 3-mm cysts within the hyperplastic mucosa impart the characteristic appearance. The hallmark of cystic hyperplasia of the gallbladder is the abundance of variably sized cystic spaces that distort and thicken the entire mucosa of the gallbladder. Most of the cysts contain a copious amount of mucus. The majority of the lining epithelial cells are typical of the normal gallbladder epithelium (i.e., tall columnar with abundant apical cytoplasmic mucus). The entire mucosa may be affected. These lesions are usually of no significance to the host. In all likelihood, cystic hyperplasia of the gallbladder frequently goes undetected visually. The cause is not known.

#### 8.2.11.5.2 Adenoma

Adenomas of the gallbladder are rare neoplasms but are most common in young cattle and have also been described in dogs, cats, and sheep. They are multinodular or papillary masses that protrude from the mucosal surface and consist of a loose connective tissue stalk that is lined with well-differentiated biliary epithelium (Fig. 8-86).

454

455

Fig. 8-85 **Cystic mucinous hyperplasia, gallbladder, dog.** The gallbladder mucosa is thickened and contains multiple mucous cysts. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia; and Noah's Arkive, College of Veterinary Medicine, The University of Georgia.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 8.2.11.5.3 Carcinoma

Malignant neoplasms of the gallbladder epithelium are rare in domestic animals but have been described in dogs, cats, and cattle. They typically are composed of mucin-secreting epithelial cells and often have a papillary arrangement. Carcinoma of the gallbladder may invade the liver by direct extension and may metastasize to the hepatic lymph nodes and to more distant sites.

### 8.2.12 DISEASES OF THE EXOCRINE PANCREAS

#### 8.2.12.1 DEVELOPMENTAL ANOMALIES

##### 8.2.12.1.1 Exocrine Pancreatic Atrophy (Juvenile Pancreatic Atrophy)

A distinct syndrome characterized by a dramatically diminished exocrine pancreas has been recognized in several breeds of dog. It is particularly common in the German shepherd dog and rough-coated collies, in which it appears to be inherited as an autosomal recessive trait. The pancreas in affected dogs is small (Fig. 8-87), but islands of normal exocrine pancreatic tissue usually remain. This lesion is most likely one of atrophy rather than hypoplasia, given recent evidence that suggests that an autoimmune pancreatitis precedes the loss of normal pancreatic parenchyma. Young animals are affected, usually between 6 to 12 months of age. Affected dogs have signs typical of maldigestion secondary to exocrine pancreatic insufficiency and rapidly lose weight despite a voracious appetite.

**Fig. 8-87 Pancreatic atrophy/hypoplasia, pancreas, dog.** Virtually no pancreatic tissue is present in this case. Pancreatic remnants are indicated by arrows. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

There may be several conditions in which the pancreas is found to be smaller than expected, and the pathogenesis of the lesions may vary depending on the species. A syndrome termed hypoplasia of the exocrine pancreas occurs sporadically in calves and is characterized by signs of exocrine pancreatic insufficiency. The distinction between atrophy and hypoplasia can be difficult to determine because both processes lead to an abnormally small organ with diminished function. Cells of the hypoplastic exocrine pancreas do not usually contain lipofuscin, which can be seen in atrophic cells.

### 8.2.12.1.2 Anomalies of the Duct System

The arrangement of the major pancreatic duct or ducts varies between and within species, so a variety of normal arrangements occur. Sheep, for instance, have only one pancreatic duct that drains into the common bile duct, whereas cattle and horses typically have two ducts, and several distinct arrangements of the pancreatic ducts have been described in dogs. The pancreatic duct of cats enters the duodenum immediately adjacent to or confluent with the common bile duct. Specific anomalies include congenital stenosis of the pancreatic ducts and cystic dilation of the ducts. Congenital cysts within the pancreas occasionally occur in lambs.

### 8.2.12.2 INCIDENTAL FINDINGS

#### 8.2.12.2.1 Ectopic Pancreatic Tissue

Nodules of ectopic pancreatic tissue sometimes are present in the duodenum or other sections of the small bowel, stomach, spleen, gallbladder, and mesentery of the dog and cat. This type of anomaly, normal tissue in an abnormal location, is termed a choristoma.

455

456

#### 8.2.12.2.2 Pacinian Corpuscles

Pacinian corpuscles are normally present within the interlobular connective tissue of the pancreas and mesentery of the cat, and appear as discrete 1- to 3-mm nodules (Fig. 8-88). The corpuscles should not be mistaken for abnormal structures.

#### 8.2.12.2.3 Autolysis

Autolysis of the pancreas is very rapid after death, particularly if the pancreas is traumatized. Postmortem release and activation of pancreatic proteolytic enzymes within the pancreas can hasten tissue breakdown. Thus autolysis may be advanced in the pancreas before it is evident in other organs. As autolysis progresses, the color of the gland may change from its normal pink to dark red or green. The metabolic activity of intestinal bacteria, which can easily gain access to the pancreas, can contribute to the discoloration of the pancreas through hemolysis and tissue decomposition.

#### 8.2.12.2.4 Pancreatic Calculi

The formation of concretions or “stones” within the pancreatic duct system is termed pancreolithiasis, and occurs uncommonly in cattle. It is usually an incidental finding at slaughter, and apparently is slightly more common in cattle older than 4 years of age than in younger animals.

## Pathologic Basis of Veterinary Disease, 4th Edition

### 8.2.12.2.5 Stromal Fat Cell Infiltration

Fat cell infiltration of the interstitial connective tissue of the pancreas occurs occasionally, especially in obese cats. The pancreas itself is usually unaffected, so exocrine pancreatic function is normal, but the dispersion of the parenchyma creates the impression that the pancreas has been replaced by adipose tissue.

**Fig. 8-88 Pacinian corpuscles (arrows), pancreas, cat.** The feline pancreas contains numerous pacinian corpuscles, which may be visible grossly as about 1-mm clear foci. (Courtesy College of Veterinary Medicine, North Carolina State University.)

### 8.2.12.3 PANCREATIC DEGENERATION AND ATROPHY

Degeneration of the acinar cells of the exocrine pancreas is a nonspecific process that can occur as a consequence of a variety of local and systemic diseases. For instance, starvation results in loss of zymogen granules within the cytoplasm of acinar cells of the exocrine pancreas because the rate of synthesis of the granules is diminished, and available protein is used to maintain serum protein concentrations when dietary protein is limited. Obstruction of the pancreatic ducts, whatever the cause, can also cause degeneration and atrophy of the exocrine pancreas. Obstruction of the pancreatic duct(s) can be caused by neoplasms or chronic inflammation and associated fibrosis that compress the duct, or by foreign bodies, such as parasites or pancreoliths, that occlude the ductal lumen. Exocrine pancreatic atrophy also may occur secondary to widespread interstitial fibrosis of the pancreas, as occurs for example, in dogs with chronic pancreatitis.

### 8.2.12.4 PANCREATIC PSEUDOCYSTS

Pancreatic pseudocysts are fluid-filled nonepithelialized fibrous sacs containing cellular debris and pancreatic enzymes that form within the pancreas or adjacent to the organ following pancreatic inflammation. They are described in dogs and cats. They should be distinguished from abscesses and cystic neoplasms.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.12.5 ACUTE PANCREATITIS/ACUTE PANCREATIC NECROSIS

Acute pancreatitis is a condition characterized primarily by necrosis and varying degrees of inflammation of the pancreas. In fact, the predominance of necrosis over inflammation supports using the term *acute pancreatic necrosis* over acute pancreatitis for dogs and cats in most instances. Obese, sedentary bitches are especially predisposed. Acute pancreatitis occurs less often in cats than dogs, but more often in cats than most other species. Acute pancreatitis has been described in a variety of species, although the cause usually is different in each species.

#### 8.2.12.5.1 Pathogenesis

The routes of injury for the pancreas include the duct system, which normally drains the organ. Obstruction of the duct(s) by migration of ascarids or flukes into the duct system, which can occur in a variety of animal species, or by pancreatic calculi, which occurs in ruminants most often, can trigger pancreatitis. Pancreatitis or acute pancreatic necrosis can also be produced by blood-borne delivery of some toxins and presumably some therapeutic drugs, notably corticosteroids. Direct trauma to the organ can also trigger pancreatitis.

456

457

There are three major proposed mechanisms of pancreatitis:

- Obstruction of the duct(s)
- Direct injury to acinar cells
- Disturbances of enzyme trafficking within the cytoplasm of acinar cells.

Obstruction of ductal flow by calculi or parasites can lead to interstitial edema that compresses small-caliber vessels and compromises local blood flow leading to ischemic damage to acinar cells. Direct damage to acinar cells can be caused by a few specific agents in animals, including compounds found in *Cassia occidentalis* and T-2 toxin, a trichothecene mycotoxin that affects pigs, and zinc toxicosis of dogs, veal calves, and sheep. Certain therapeutic drugs, such as sulfonamides and potassium bromide-phenobarbital combinations, can damage the pancreas in dogs, and other species are probably similarly affected. Ischemia to the pancreas from a variety of causes may also produce direct injury to the acinar cells. A third mechanism involves aberrant transport of proenzymes within the acinar cells, leading to inappropriate activation of the enzymes within the cells. The association between corticosteroid administration in dogs and an increased risk of acute pancreatitis could possibly be explained by this mechanism. However, many cases of acute pancreatitis commonly occur after dogs have consumed a meal high in fat or some other dietary indiscretion, and the specific mechanism triggering the disease remain unclear. Pancreatitis is occasionally initiated by trauma, usually in dogs and cats as a consequence of some accidental crushing or impact trauma to the abdomen or surgical trauma. Leakage of enzymes from the pancreas initiates necrosis, followed by trauma and inflammation of the pancreas and adjacent tissue in the same manner as previously described for pancreatitis in the dog.

Acute pancreatitis in dogs occurs as a consequence of release of activated pancreatic enzymes into the pancreatic parenchyma and adjacent tissue producing autodigestion. Trypsin is believed to be a key player in pancreatitis. Once activated, trypsin in turn can activate proelastase and phospholipase into elastase and phospholipase A. These enzymes digest pancreatic tissue and adjacent fat, and damage blood vessels. Trypsin also activates prekallikrein, leading to involvement of the kinin system, complement, and clotting

## Pathologic Basis of Veterinary Disease, 4th Edition

---

cascades in affected tissue. These in turn amplify the process, promote thrombosis and hemorrhage, and attract inflammatory cells.

The pancreas is protected by the continuous flow of secretions into the duodenum, which prevents reflux of duodenal contents. The normal secretion of the pancreas contains trypsin, chymotrypsin, elastase, aminopeptidases, lipase, phospholipases, amylase, and nucleases. Trypsin is a critical enzyme because it has a role in the activation of several of the other pancreatic enzymes. Several mechanisms exist to protect the healthy pancreas from the effects of digestive enzymes it produces. Before secretion, enzymes are isolated from the acinar cell cytoplasm in membrane-bound zymogen granules. Most enzymes, except amylase and lipase, are secreted as proenzymes to prevent pancreatic injury. In particular, trypsin activation is tightly controlled because of its central role in activation of other enzymes. Consequently, the proenzyme trypsinogen is not normally activated until it enters the lumen of the duodenum through duodenal enteropeptidase. In addition, the chance of inappropriate trypsin activation in acinar cells or ducts of the pancreas is reduced by secretion of protective trypsin inhibitors. In circumstances in which trypsin or other enzymes are inappropriately activated, there are several other defenses in place. Acinar cells have an innate resistance to several of the digestive enzymes. Intrapancreatic release of active enzymes triggers the release of other enzymes that will degrade the offending digestive enzymes, and lysosomal enzymes can degrade the zymogen granules when the pancreatic secretion is disturbed, reducing the burden of potentially injurious enzymes.

Direct trauma to the pancreas is uncommon, except during surgical manipulations, because the organ has a central location within the abdomen and is protected from all but serious physical trauma.

The gross lesions of acute pancreatitis are referable to proteolytic degradation of pancreatic parenchyma, vascular damage and hemorrhage, and necrosis of peripancreatic fat by lipolytic enzymes of the pancreas. Mild cases of pancreatitis are characterized by edema of the interstitial tissue of the pancreas. Acute hemorrhagic pancreatitis is more severe, and characteristically the pancreas is edematous and contains areas that are gray-white, the result of coagulation necrosis, and other areas that are dark red or blue-black, which are hemorrhagic (Fig. 8-89, A). Areas of fat necrosis are manifest as chalky-white foci as a result of saponification of necrotic adipose tissue in the mesentery adjacent to the pancreas. Portions of normal pancreatic parenchyma may be interspersed between affected portions. The peritoneal cavity frequently contains blood-stained fluid, which may contain droplets of fat in the early stage. Peritonitis is manifest by fibrinous adhesions between the affected portions of the pancreas and adjacent tissues.

The microscopic appearance of acute hemorrhagic pancreatitis reflects the gross lesions just described. Characteristic lesions include focally extensive areas of hemorrhage, influx of leukocytes, and coagulation necrosis of the pancreatic parenchyma, accumulation of fibrinous exudate in the interlobular septa, and necrosis and inflammation of fat in the mesentery adjacent to the affected portions of pancreas (Fig. 8-89, B).

457

458

Fig. 8-89 **Acute pancreatic necrosis, acute pancreatitis, pancreas, dog.**

**A**, Note the expansion of the pancreas by areas of hemorrhage and edema. **B**, Acute pancreatitis (histologic appearance of the pancreas depicted in Fig. 8-89, **A**). Note the accumulation of fibrinous exudate and edema within the interlobular septa (**S**) and inflammatory cell infiltrate (**I**). H&E stain. (**A**, Courtesy Dr. R. Fairley. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Species differences in acute pancreatitis are recognized. For example, in cats there appears to be two distinct syndromes of acute pancreatitis, one characterized by an acute pancreatic necrosis and a distinct suppurative pancreatitis that is most likely the consequence of ascending bacterial infection.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Acute pancreatitis is usually characterized by vomiting, diarrhea, anorexia, and abdominal tenderness. Acute, severe pancreatitis also produces systemic effects in affected dogs. The release of inflammatory mediators and activated enzymes from the damaged pancreas may produce widespread vascular injury and subsequent widespread hemorrhage, shock, and disseminated intravascular coagulation. The liver also is affected in many cases of pancreatitis, as indicated by increased concentrations of serum hepatic enzymes (such as alanine aminotransferase), and sometimes, focal hepatic necrosis.

The pancreas possesses modest regenerative capacity following acute pancreatitis with necrosis of pancreatic exocrine epithelial cells, although more robust regeneration following partial pancreatectomy has been shown. Acinar cells can undergo replication in cases of limited injury, and precursor cells arise from cells within or adjacent to ductal epithelium in more severe injury. Following acute pancreatic injury, there is usually little evidence of regeneration of the exocrine pancreas if there has been sufficient tissue destruction. Fibrosis is the principal response to exocrine pancreatic injury. Proliferated ductules and atrophic exocrine pancreatic lobules are also found following significant pancreatic injury.

Acute pancreatitis sufficient to cause clinical disease apparently is considerably less common in species other than the dog and cat. Acute pancreatic necrosis and pancreatitis have been described in the horse, but the pathogenesis of pancreatitis in this species differs from that in the dog and cat. Necrosis and inflammation are the result of migration of strongyle larvae through the pancreas, which results in the release of pancreatic enzymes and enzymatic digestion of the pancreas and surrounding tissue.

8.2.12.6

### CHRONIC PANCREATITIS

Chronic pancreatitis is typically accompanied by fibrosis and parenchymal atrophy. It can occur in all species as a consequence of obstruction of the pancreatic ducts and presumably all of the other mechanisms associated with acute pancreatitis. Chronic inflammation of the pancreas, characterized by lymphoplasmacytic infiltrates, is most common and important in the dog, but does occur in the cat, horse, and cattle, in which it is rarely of clinical significance. In the dog, pancreatic fibrosis and chronic pancreatitis are the result of progressive destruction of the pancreas by repeated mild episodes of acute pancreatic necrosis and pancreatitis. The pancreas has modest regenerative capacity and responds to injury with replacement fibrosis and atrophy of persisting parenchyma. Thus ongoing destruction of pancreatic tissue will cause progressive loss of glandular tissue without replacement (Fig. 8-90). If a significant portion of the pancreas is affected, dogs may develop signs of exocrine pancreatic insufficiency, with or without signs of endocrine pancreatic insufficiency (diabetes mellitus). Grossly the pancreas in affected animals is a distorted, shrunken, nodular mass with fibrous adhesions to adjacent tissue. Destruction of pancreatic tissue frequently is not of sufficient magnitude to cause exocrine pancreatic insufficiency, and pancreatic fibrosis is sometimes found as incidental lesions at necropsy of dogs with apparently normal digestive function. Fibrosis of the exocrine pancreas also occurs with some frequency in cats and following the necrosis of exocrine pancreatic cells from zinc toxicosis in sheep. Ectasia of the pancreatic ducts with cyst formation also is relatively common in cats with interstitial pancreatic fibrosis.

458

459

**Fig. 8-90 Chronic pancreatitis, pancreas, dog.** **A**, Lobules are more prominent due to fibrosis, and the pancreas is paler than normal. The white, raised, granular areas in the pancreas and mesentery are foci of fat necrosis that result from enzymatic digestion of lipids that then become mineralized. **B**, Remaining exocrine pancreatic cells are separated into small lobules by abundant fibrous connective tissue (*F*), which contains chronic inflammatory cells (*arrow*). H&E stain. (**A**, Courtesy College of Veterinary Medicine, North Carolina State University. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Chronic pancreatitis and replacement fibrosis occurs sporadically in the horse, usually as a consequence of either parasitic migration or from ascending bacterial infection of the pancreatic ducts. In addition, pancreatitis may occur in horses with chronic eosinophilic gastroenteritis. However, chronic pancreatitis usually is not clinically apparent in the horse, as signs of exocrine pancreatic insufficiency rarely, if ever, occur in this species.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 8.2.12.7 PARASITIC INFECTIONS

A variety of parasites may inhabit the pancreatic ducts of domestic animals. Parasitic infections of the pancreatic ducts are important if they occlude the ducts, either by direct physical obstruction or by inducing inflammation within and around ducts. Examples include flukes of the families Opisthorchiidae (*Opisthorchis tenuicollis*, *Opisthorchis viverrini*, *Clonorchis sinensis*, *Metorchis albidus*, *Metorchis conjunctus*) and Dicrocoeliidae (*Eurytrema pancreaticum*, *Concinnum procyonis*, *Dicrocoelium dendriticum*), which may inhabit the pancreatic ducts of a variety of animal species. Nematodes, particularly ascarids, and cestodes are common gastrointestinal parasites of the domestic species; occasionally, they may lodge within the pancreatic ducts.

### 8.2.12.8 HYPERPLASIA AND NEOPLASIA

#### 8.2.12.8.1 Pancreatic Nodular Hyperplasia

Nodular hyperplasia of the exocrine pancreas occurs in dogs, cats, and cattle. It is especially common in older dogs and cats. The lesion is of no clinical significance, but it must be distinguished from neoplasms of the endocrine and exocrine pancreas.

These hyperplastic nodules typically are multiple, raised, smooth, and a uniform gray or white on a cut surface (Fig. 8-91, A). The nodules may be firmer than the adjacent normal pancreas. Microscopically, these nodules consist of unencapsulated aggregates of acinar cells that may lack zymogen granules or contain an abundance of them (Fig. 8-91, B). Some nodules contain a mixture of the two types of acinar cells. The distinction between hyperplasia and adenoma of the exocrine pancreas is poorly defined in domestic animals.

#### 8.2.12.8.2 Pancreatic Adenoma

Adenomas of the exocrine pancreas are extremely rare but have been described in the cat. Those of acinar cell origin share all the features of hyperplastic nodules, but are single and larger than normal pancreatic lobules, whereas hyperplastic nodules are not larger than normal lobules; this distinction clearly is somewhat arbitrary.

#### 8.2.12.8.3 Pancreatic Carcinoma

Carcinoma of the ductular epithelium or acinar cells of the exocrine pancreas is uncommon in all species. It is most often reported in the dog and cat. The neoplasms may consist of single or multiple nodules of variable size within the pancreas, each of which consists of gray or yellow tissue. Lesions may consist of a single nodule or affect the organ diffusely. Tumors are typically grayish-white to pale yellow with a firm to hard consistency (Fig. 8-92, A). Tumors are often gritty when cut. Areas of hemorrhage, mineralization, or necrosis may be present within the neoplasm. The neoplasm is usually firmer than the adjacent pancreas because of proliferation of fibrous connective tissue. Adhesion of the affected pancreas to adjacent tissue may occur. This neoplasm often invades adjacent tissue and seeds the peritoneal cavity. Peritoneal implants form nodules over the mesentery, omentum, and serosa of the abdominal viscera. Metastasis to the regional lymph nodes (pancreatoduodenal, which is inconstantly present and the right hepatic lymph node) is also common, and some carcinomas metastasize widely.

459

460

## Pathologic Basis of Veterinary Disease, 4th Edition

Microscopic features of carcinomas of the exocrine pancreas range from well-differentiated adenocarcinomas with tubular patterns to undifferentiated carcinomas with solid patterns. The amount of fibrous stroma varies considerably, and usually is greatest in poorly differentiated neoplasms (Fig. 8-92, B). Zymogen granules similar to those present in normal acinar cells of the pancreas are often absent within the cytoplasm of the neoplastic cells. Mitotic figures are common.

**Fig. 8-91 Pancreatic nodular exocrine hyperplasia, pancreas, dog.** **A,** Hyperplastic nodules are pale beige to white and project above the surface. **B,** Microscopically hyperplastic nodules (*N*) are composed of numerous small acini, most of which, in this case, lack typical zymogen granules. H&E stain. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Dr. J.M. Cullen, College of Veterinary Medicine, North Carolina State University.)

Fig. 8-92 **Pancreatic carcinoma.** **A**, Stomach and pancreas (*center*), ventral-dorsal view, dog. Pancreatic carcinoma has invaded the mesentery, wall of the stomach, and gastrosplenic ligament. Note the lobulated appearance of the mass, which is formed by neoplastic exocrine pancreatic epithelial cells and scirrhous connective tissue. Proximal duodenum (*bottom*), liver (*top*), and spleen (*right [left anatomically]*). **B**, Pancreas, cat. Pancreatic carcinoma tends to form crude acini or tubules that aggressively invade adjacent normal tissue. Prominent fibrosis, termed scirrhous response, is commonly caused by this type of tumor. ## 9 Chapter 9 Respiratory System

ALFONSO LÓPEZ

### 9.1 INTRODUCTION

Diseases of the respiratory system are some of the leading causes of morbidity and mortality in animals and a major source of economic losses. Thus veterinarians are routinely called to diagnose, treat, and implement health management practices to reduce the impact of these diseases. In companion animals, diseases of the respiratory tract are also common and, although of little economic significance, are important to the health of the animals and thus to clinicians and owners.

#### 9.1.1 STRUCTURE AND FUNCTION

To facilitate the understanding of the structure and function, it is convenient to arbitrarily divide the respiratory system into conducting, transitional, and gas exchange systems (Fig. 9-1). The conducting system includes nasal cavity, paranasal sinuses, pharynx, larynx, trachea, and extrapulmonary and intrapulmonary bronchi, all of which are largely lined by pseudostratified, ciliated columnar cells plus a variable proportion of secretory goblet (mucous) and serous cells (Figs. 9-2, 9-3, and 9-4). The transitional system of the respiratory tract is composed of bronchioles, which serve as a transition zone between the conducting system (ciliated) and the gas exchange (alveolar) system (Fig. 9-1). The disappearance of cilia in the transitional system is not abrupt; the ciliated cells in the proximal bronchiolar region become scarce and progressively attenuated, until the point where distal bronchioles no longer have ciliated cells. Normal bronchioles also lack goblet cells, but instead have other types of secretory cells, notably Clara and neuroendocrine cells. Clara cells contain numerous biosynthetic organelles that play an active role in detoxification of xenobiotics (foreign substances), similar to the role of hepatocytes. In carnivores and monkeys, and to a much lesser extent in horses and human beings, the terminal portions of bronchioles are not only lined by cuboidal epithelium but also by segments of alveolar capillaries. These unique bronchioloalveolar structures are known as respiratory bronchioles (Fig. 9-1). The gas exchange system of the respiratory tract in all mammals is formed by alveolar ducts and millions of alveoli (Fig. 9-5). Alveoli are superficially lined by two distinct types of epithelial cells known as type I pneumonocytes (membranous) and type II pneumonocytes (granular) (Fig. 9-6).

All three—the conducting, transitional and exchange systems of the respiratory system—are vulnerable to injury because of constant exposure to a myriad of microbes, particles and fibers, and toxic gases and vapors present in the air. Vulnerability of the respiratory system to aerogenous (airborne) injury is primarily because of (1) the extensive area of the alveoli, which are the interface between the respiratory system and inspired air; (2) the large volume of air passing continuously into the lungs; and (3) the high concentration of noxious elements that can be present in the air (Table 9-1). For human beings, it has been estimated that the surface of the pulmonary alveoli is approximately 200 m<sup>2</sup>, roughly the area of a tennis court. It has also been estimated that the volume of air reaching the human lung every day is around 9000 L. The surface of the equine lung is estimated to be around 2000 m<sup>2</sup>.

463

464

Fig. 9-1 **Schematic diagram of airways from the trachea to the alveoli.** Conducting, transitional, and exchange components of the respiratory system. The transitional zone (bronchioles) is not present or as equally well developed in all species. (From Banks WJ: Applied veterinary histology, ed 3, St Louis, 1993, Mosby.)

Fig. 9-2 **Schematic representation of the mucociliary carpet that covers the conducting system.** Both ciliated and goblet cells rest on the basement membrane. Mucus produced and released by goblet cells forms a carpet on which inhaled particles (*dots*) are trapped and subsequently expelled into the pharynx by the mucociliary apparatus. (Courtesy Dr. A. López, Atlantic Veterinary College.)

**Fig. 9-3 Normal bronchial mucosa, bronchus, rat.** The mucous layer was removed before fixation to expose the external surface of the epithelium. Mucosa consists of ciliated cells and nonciliated secretory cells. Ciliated cells have numerous slender cilia (*arrows*). Nonciliated secretory cells have a dome-shaped surface with abundant microvilli (*arrowheads*). The proportion of ciliated to nonciliated cells varies depending on the level of airways. Ciliated cells are more abundant in proximal airways, whereas secretory cells are more numerous in distal portions of the conducting and transitional systems. Scanning electron micrograph. Carbon sputter coating method. (*Courtesy Dr. A. López, Atlantic Veterinary College.*)

Fig. 9-4 **Normal ciliated epithelium, trachea, cow.** This trachea was specially fixed to preserve the mucous layer, which consists of an internal, clear, hypophase-fluid layer (not visible here) surrounding microvilli and kinocilia and an external mucous epiphase at the level of the tips of the kinocilia (cut in both transverse and longitudinal section here). TEM. Uranyl acetate and lead citrate stain. (From Sims DE, Westfall JA, Kiorpes AL, Horne MM: Biotech Histochem 66:173-180, 1991.)

Fig. 9-5 **Lung, rat.** Lungs were fixed by intratracheal perfusion of fixative to retain normal distention of airways. Note the dichotomous branching of the bronchioles and the slender visceral pleura covering the surface of the lungs. B, Branching bronchioles; \*, alveoli; arrow, visceral pleura. H&E stain. (Courtesy Dr. J. Martínez-Burnes, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Lungs are also susceptible to blood-borne (hematogenous) microbes, toxins, and emboli. This fact is not surprising because the entire cardiac output of the right ventricle goes into the lungs, and approximately 9% of the total blood volume is within the pulmonary vasculature. Also the pulmonary capillary bed is the largest in the body, with a surface area of  $70 \text{ m}^2$  in the adult human being; this area is equivalent to a length of 2400 km of capillaries, with 1 ml of blood occupying up to 16 km of capillary bed.

464

465

**Fig. 9-6 The blood-air barrier.** **A**, In this schematic diagram, note the thin membrane separating the blood compartment from the alveoli. Type I alveolar cells (membranous pneumonocytes) are remarkably thin and cover most of the alveolar wall. Note the endothelial cells lining the alveolar capillary. Alveolar interstitium supports the alveolar epithelium on one side and the endothelium on the other side of the blood-air barrier. Type II (granular) pneumonocytes appear as large cuboidal cells with lamellar bodies (surfactant) in the cytoplasm. A pulmonary intravascular macrophage, a component of the monocyte-macrophage system, is depicted on the wall of an alveolar capillary. A red blood cell (RBC) is present inside the lumen of the alveolar capillary. **B**, Alveolar wall. The blood-air barrier consists of cytoplasmic extensions of (1) type I alveolar cells (membranous pneumonocytes); (2) a dual basal lamina synthesized by type I alveolar cells; (3) cytoplasmic extensions of endothelial cells. TEM. Uranyl acetate and lead citrate stain. (**A**, Courtesy Dr. A. López, Atlantic Veterinary College. **B**, From Kierszenbaum AL: Histology and cell biology, St Louis, 2002, Mosby.)

## Pathologic Basis of Veterinary Disease, 4th Edition

### 9.1.2 NORMAL FLORA OF THE RESPIRATORY SYSTEM

The respiratory system has its own normal bacterial flora, as does any other body system in contact with the external environment. If a sterile swab is passed deep into the nasal cavity of any healthy animal and cultured for microbes, many species of bacteria are recovered, such as *Mannheimia (Pasteurella) haemolytica* in cattle; *Pasteurella multocida* in cats, cattle, and pigs; and *Bordetella bronchiseptica* in dogs and pigs. The organisms that constitute the normal flora of the respiratory tract are restricted to the most proximal (rostral) region of the conducting system (nasal cavity, pharynx, and larynx). The thoracic portions of the trachea, bronchi, and lungs are considered to be essentially sterile. The types of bacteria present in the nasal flora vary considerably among animal species and in different geographic regions of the world. Some bacteria present in the nasal flora are pathogens that can cause important respiratory infections. For instance, *Mannheimia (Pasteurella) haemolytica* is part of the bovine nasal flora, yet this bacterium causes a devastating disease in cattle—pneumonic manheimiosis (shipping fever). Experimental studies have established that microorganisms from the nasal flora are continuously carried into the lungs via tracheal air. In spite of this constant bacterial bombardment from the nasal flora and from contaminated air, normal lungs remain sterile because of their remarkably effective defense mechanisms.

465

466

**Table 9-1 Common Pathogens, Allergens, and Toxic Substances Present in Inhaled Air**

Microbes	Viruses, <i>Chlamydophila</i> , bacteria, fungi, protozoa
Plant dust	Grain, flour, cotton, wood
Animal products	Dander, feathers, mites, insect chitin
Toxic gases	Ammonia (NH <sub>3</sub> ), hydrogen sulfide (H <sub>2</sub> S), nitrogen dioxide (NO <sub>2</sub> ), sulfur dioxide (SO <sub>2</sub> ), chlorine
Chemicals	Organic and inorganic solvents, herbicides, asbestos, nickel, lead

### 9.1.2.1 Box 9-1 Portals of Entry into the Respiratory System

Aerogenous (air)	Virus, bacteria, <i>Chlamydophila</i> , fungi, toxic gases, and pneumotoxins
Hematogenous (blood)	Virus, bacteria, fungi, parasites, toxins, and pneumotoxins
Direct extension	Penetrating wounds, migrating awns, bites, and ruptured esophagus or perforated diaphragm (hardware)

### 9.1.3 PORTALS OF ENTRY INTO THE RESPIRATORY SYSTEM

Microbes, toxins, and pneumotoxins can gain access into the respiratory system by the following routes (Box 9-1):

1. Aerogenous—Pathogens, such as bacteria, mycoplasmas, and viruses, along with toxic gases and foreign particles, including food, can gain access to the respiratory system via inspired air. This is the most common route in the transmission of most respiratory infections in domestic animals.
2. Hematogenous—Some viruses, bacteria, parasites, and toxins can enter the respiratory system via the circulating blood. This portal of entry is commonly seen in septicemias, sepsis, protozoal infections, and

## Pathologic Basis of Veterinary Disease, 4th Edition

viruses that target endothelial cells. Also, circulating leukocytes may release infectious organisms such as retroviruses and *Listeria monocytogenes* while traveling through the lungs.

3. Direct extension—In some instances pathogenic organisms can also reach the pleura and lungs through penetrating injuries, such as gunshot wounds, migrating awns, bites, or by direct extension from a ruptured esophagus or perforated diaphragm.

### 9.1.4

#### DEFENSE MECHANISMS OF THE RESPIRATORY SYSTEM

It is axiomatic that a particle, microbe, or toxic gas must first gain entry to a vulnerable region of the respiratory system before it can have a pathologic effect. The characteristics of size, shape, dispersal, and deposition of particles present in inspired air are studied in aerobiology. It is important to recognize the difference between deposition and retention of inhaled particles. Deposition is the process by which particles of various sizes and shapes are trapped within specific regions of the respiratory tract. Clearance is the process by which deposited particles are destroyed, neutralized, or removed from the mucosal surfaces. The main mechanisms involved in clearance are sneezing, coughing, mucociliary transport, and phagocytosis (Box 9-2). The difference between what is deposited and what is cleared from the respiratory tract is referred to as retention. Abnormal retention of particles resulting from increased deposition, decreased clearance, or a combination of both, is the underlying pathogenetic mechanism in many pulmonary diseases (Fig. 9-7).

The anatomic configuration of the nasal cavity and bronchi in the conducting system plays a unique role in preventing or reducing the penetration of noxious material into the lungs, especially into the alveolar region, which is the most vulnerable portion of the respiratory system. The narrow nasal meatuses and the coiled arrangement of the nasal conchae generate enormous turbulences of airflow and, as a result, physical forces are created that forcefully impact particles larger than 10  $\mu\text{m}$  onto the surface of the nasal mucosa (Fig. 9-8).

466

467

Although particles smaller than 10  $\mu\text{m}$  could escape trapping in the nasal cavity, these medium-sized particles meet a second barrier at the tracheal and bronchial bifurcations. Here, abrupt changes in the direction of air (inertia), which occurs at the branching of major airways, cause particles in the 2- to 10- $\mu\text{m}$  size range to collide with the surface of bronchial mucosa (Fig. 9-1). Because the velocity of inspired air at the level of the small bronchi and bronchioles has become rather slow, inertial and centrifugal forces no longer play a significant role in the trapping of inhaled particles. Here, in the transitional (bronchiolar) and exchange (alveolar) regions, particles 2  $\mu\text{m}$  or smaller may come into contact with the mucosa by means of sedimentation because of gravitation or by diffusion as a result of Brownian movement. Infective aerosols containing bacteria and viruses are within the size ranges (0.01 to 2  $\mu\text{m}$ ) that gain access to the bronchioloalveolar region.

### 9.1.4.1

#### Box 9-2 Main Defense Mechanisms of the Respiratory System

Conducting system (nose, trachea and bronchi)	Mucociliary clearance, antibodies, lysozyme, mucus
Transitional system (bronchioles)	Clara cells, antioxidants, lysozyme, antibodies
Exchange system (alveoli)	Alveolar macrophages (inhaled pathogens), intravascular macrophages (circulating pathogens), opsonizing antibodies, surfactant, antioxidants

**Fig. 9-7 Pulmonary clearance and retention of bacteria following inhalation of an experimental aerosol of bacteria.** When large numbers of bacteria are inhaled, the normal defense mechanisms promptly eliminate these microorganisms from the lungs (*blue line*). However, when the defense mechanisms are impaired by a viral infection, lung edema, stress, etc., the inhaled bacteria are not eliminated but colonize and multiply in the lung (*red line*). (Courtesy Dr. A. López, Atlantic Veterinary College.)

In addition to size, other factors, such as shape, length, electrical charge, and humidity, play an important role in mucosal deposition, retention, and pathogenicity of inhaled particles. For instance, particles longer than 200  $\mu\text{m}$  may also reach the lower respiratory tract, provided their mean aerodynamic diameter is less than 1  $\mu\text{m}$ . Asbestos is a good example of a large but slender fiber that can bypass the filtrating mechanisms by traveling parallel to the airstream. Once in the lungs, asbestos fibers cause asbestosis, a serious pulmonary disease in human beings. In summary, the anatomic features of the nasal cavity and airways provide an effective barrier, preventing the penetration of most large particles into the lungs.

**Fig. 9-8 Dorsal (D), ventral (V), and ethmoidal (E) conchae, midsagittal section of head, cow.** These narrow meatuses (*spaces between arrows*) and the air turbulence produced in the meatuses by the coiled arrangement of the conchae cause suspended particles to impact on the mucus covering the surface of the nasal mucosa. These particles are then moved caudally by the mucociliary escalator and finally swallowed. Note the abundant lymphoid tissue (LT) in the nasopharynx. (Courtesy Dr. R.G. Thomson, Ontario Veterinary College.)

Once larger particles are trapped in the mucosa of conducting airways and small particles are deposited on the surface of the bronchioalveolar mucosa, it is crucial that these exogenous materials be removed to prevent or minimize injury to the respiratory system. For these purposes, the respiratory system is equipped with several defense mechanisms, all of which are provided by specialized cells operating in a remarkably well-coordinated manner.

### 9.1.5

#### DEFENSE MECHANISMS OF THE CONDUCTING SYSTEM (NOSE, TRACHEA, AND BRONCHI)

Mucociliary clearance is the physical unidirectional movement and removal of deposited particles and gases dissolved in the mucus from the respiratory tract. Mucociliary clearance is provided by the mucociliary blanket (mucociliary escalator) and is the main defense mechanism of the conducting system (nasal cavity, trachea, and bronchi) (Figs. 9-2 and 9-4). Mucus is a complex mixture of water, glycoproteins, immunoglobulins, lipids, and electrolytes produced by goblet (mucous) cells, serous cells, submucosal glands, and fluid from transepithelial ion and water transport. Once serous fluid and mucus are secreted onto the surface of the respiratory mucosa, a thin, double-layer film of mucus is formed on top of the cells. The outer layer of this film is in a viscous gel phase, whereas the inner layer, which is in a fluid or sol phase, is directly in contact with cilia (Fig. 9-4). A healthy human being produces around 100 ml of mucus per day. Each ciliated cell in the conducting system has around 250 cilia (6  $\mu$ m long), beating metachronously (forming a wave) at approximately 1000 strokes per

467

468

## Pathologic Basis of Veterinary Disease, 4th Edition

minute, and in a horse, for instance, mucus moves longitudinally up to 20 mm per minute. Rapid and powerful movement of cilia creates a series of waves that, in a continuous and synchronized manner, propel the mucus, exfoliated cells, and trapped particles out of the respiratory tract. The mucus is finally swallowed, or when present in large amounts, it is coughed up out of the conducting system. If mucus flow were to move at the same rate in all levels of a conducting system, a “bottleneck” effect would be created in major airways as the minor but more numerous airways enter the bronchi. For this reason, the mucociliary transport in proximal (rostral) airways is physiologically faster than that of the distal (caudal) ones.

The mucociliary blanket of the nasal cavity, trachea, and bronchi also plays an important role in preventing injury from toxic gases. If a soluble gas contacts the mucociliary blanket, it mixes with the mucus, thus reducing the concentration of gas reaching deep into the alveoli. In other words, mucus acts as a “scavenger system,” whereby gases are solubilized and subsequently cleared from the respiratory tract via mucociliary transport. If ciliary transport is reduced (loss of cilia) or mucus production is excessive, coughing becomes an important mechanism for clearing the airways.

In addition to the physical transport provided by the mucociliary escalator, other cells closely associated with ciliated epithelium contribute to the defense mechanism of the conducting system. Among the most notable ones are the M cells (“microfold cells”), which are modified epithelial cells covering the bronchial associated lymphoid tissue (BALT), both of which are strategically located at the corner of the bifurcation of bronchi and bronchioles, where inhaled particles often collide with the mucosa because of inertial forces. From here, inhaled particles and soluble antigens are phagocytosed and transported by macrophages, dendritic cells, and other professional “antigen-presenting cells” (APCs) into the BALT, thus providing a unique opportunity for B and T lymphocytes to enter into close contact with inhaled pathogenic substances. Pulmonary lymphocytes are not quiescent in the BALT but are in continual traffic to other organs and contribute to both cellular (cytotoxic, helper, suppressor T lymphocytes) and humoral immune responses. Immunoglobulin (Ig)A, produced by mucosal plasma cells, and to a lesser extent, IgG and IgM play important roles in the local immunity of the conducting system, especially with regard to preventing attachment of pathogens to the mucociliary blanket. Chronic airway diseases, especially those due to infection—such as those caused by mycoplasmas or retroviruses—are often accompanied by severe hyperplasia of the BALT.

The mucociliary clearance terminates at the pharynx, where mucus, propelled caudally from the nasal cavity and cranially from the tracheobronchial tree, is eventually swallowed and thus eliminated from the conducting system of the respiratory tract. Some respiratory pathogens such as *Rhodococcus equi* can infect the intestines after having been removed and swallowed from the respiratory tract into the alimentary system.

9.1.6

### DEFENSE MECHANISMS OF THE EXCHANGE SYSTEM (ALVEOLI)

Alveoli lack ciliated and mucus-producing cells; thus the defense mechanism against inhaled particles in the alveolar region cannot be provided by mucociliary clearance. Instead the main defense mechanism of alveoli (exchange system) is phagocytosis provided by the pulmonary alveolar macrophages (Fig. 9-9). These highly phagocytic cells are derived largely from blood monocytes and, to a much lesser extent, from a slowly dividing population of interstitial macrophages. After a temporary adaptive stage within pulmonary interstitium, blood monocytes reduce their glycolytic and increase their oxidative metabolism to function in an aerobic rather than in an anaerobic environment. Pulmonary alveolar macrophages rapidly attach and phagocytose bacteria and any other particle reaching the alveolar region. The number of macrophages in the alveolar space is closely related to the number of inhaled particles reaching the lungs. This ability to increase, within hours, the number of available phagocytic cells is vital in protecting the distal lungs against foreign material, particularly when the inhaled particle load is high. Unlike that of tissue macrophages, the life span of alveolar macrophages in the alveoli is notably short, only a few days, and thus they are continuously being replaced.

468

469

**Fig. 9-9 Pulmonary alveolar macrophages.** **A**, Bronchoalveolar lavage, healthy pig. Alveolar macrophages characterized by abundant and vacuolated cytoplasm are the predominant cell in lavages from healthy lungs. **B**, Alveolar macrophage, rat. Note abundant cytoplasm with numerous phagolysosomes and elongated pseudopods extending from the cell surface. TEM. Uranyl acetate and lead citrate stain. (**A**, Courtesy Dr. L.A. Rijana-Ludbit, Tübingen. **B**, Courtesy Dr. A. López, Atlantic Veterinary College.)

Alveolar phagocytosis plays a prominent role in the innate defense mechanism against inhaled bacteria without the need of an inflammatory reaction. Bacteria reaching the alveoli are rapidly phagocytosed, and bactericidal enzymes present in lysosomes are discharged into the phagosome containing the bacteria (Fig. 9-9). Except for some facultative pathogens that are resistant to intracellular killing (e.g., *Mycobacterium tuberculosis*, *Listeria monocytogenes*, *Brucella abortus*, some *Salmonella* spp.), most bacteria reaching the lungs are rapidly destroyed by activated alveolar macrophages. Similarly, inhaled particles, such as dust, pollen, spores, carbon, or erythrocytes from intraalveolar hemorrhage, are all phagocytosed and eventually removed from alveoli by pulmonary alveolar macrophages. Most alveolar macrophages leave the alveoli by migrating toward the bronchiolar (transitional) region until the mucociliary blanket is reached. Once there, pulmonary macrophages are removed in the same way as any other particle, which is, along the mucociliary flow to the pharynx and swallowed.

Destruction and removal of inhaled microbes and particles by alveolar macrophages is a well-orchestrated mechanism that engages many cells and pulmonary secretions in the lung. The cell-to-cell interactions are complex and involve pulmonary alveolar macrophages, pneumonocytes, endothelial cells, lymphocytes, plasma cells, and dendritic cells. Antibodies are also important in the protection (acquired immune response) of the respiratory tract against inhaled pathogens. IgA is the most abundant antibody in the nasal and tracheal secretions and prevents the attachment and absorption of antigens (immune exclusion). IgG, and to a lesser extent IgE and IgM, promote the uptake and destruction of inhaled pathogens by phagocytic cells (immune elimination). IgG is the most abundant antibody in the alveolar surface and acts primarily as an opsonizing antibody for alveolar macrophages and neutrophils. In addition to antibodies, there are several secretory products locally released into the alveoli that constitute the alveolar lining material and contribute to the

## Pathologic Basis of Veterinary Disease, 4th Edition

pulmonary defense mechanisms. The most important of these antimicrobial products are transferrin, anionic peptides, and pulmonary surfactant (Table 9-2).

To facilitate phagocytosis and discriminate between “self” and “foreign” antigens, pulmonary alveolar macrophages are furnished with a wide variety of specific receptors on their cell surfaces. Among the most important ones are Fc receptors for antibodies; complement receptors (C3b, C3a, C5a); tumor necrosis factor (TNF) receptor; and CD40 receptors, which facilitate phagocytosis; and destruction of opsonized particles.

469

Toll-like receptors recognize microbial components, and FAS receptors are involved in apoptosis and in the phagocytosis of apoptotic cells in the lung. “Scavenger receptors,” which are responsible for the recognition and uptake of foreign particulates, such as dust and fibers, are also present on pulmonary alveolar macrophages.

470

**Table 9-2 Defense Mechanisms Provided by Some Cells and Secretory Products Present in the Respiratory System**

Cell/Secretory Product	Action
Alveolar macrophage	Phagocytosis, main line of defense against inhaled particles and microbial pathogens in the alveoli
Intravascular macrophage	Phagocytosis, removal of particles, endotoxin, and microbial pathogens in the circulation
Ciliated cells	Expel mucus and inhaled particles and microbial pathogens by ciliary action
Clara cells	Detoxification of xenobiotics (mixed function eto oxidases) and protective secretions against oxidative stress and inflammation
Mucus	Traps inhaled particles and microbial pathogens and neutralizes soluble gases
Surfactant	Protects alveolar walls and enhances phagocytosis
Lysozyme	Antimicrobial enzyme
Transferrin and lactoferrin	Inhibition and suppression of bacterial growth
$\alpha_1$ -Antitrypsin	Protects against the noxious effects of proteolytic enzymes release by phagocytic cells; also inhibits inflammation
Interferon	Antiviral agent and modulator of the immune and inflammatory responses
Interleukins	Chemotaxis, up-regulation of adhesion molecules
Antibodies	Prevent microbe attachment to cell membranes, opsonization
Complement	Chemotaxis; enhances phagocytosis
Antioxidants*	Prevent injury caused by superoxide anion, hydrogen peroxide, and free radicals generated during phagocytosis, inflammation, or by inhalation of oxidant gases (ozone, NO <sub>2</sub> , SO <sub>2</sub> )

\* Superoxide dismutase, catalase, glutathione peroxidase, oxidant free radical scavengers (tocopherol, ascorbic acid).

9.1.7

### DEFENSE MECHANISMS AGAINST BLOOD-BORNE PATHOGENS (INTRAVASCULAR SPACE)

Lungs are also susceptible to hematogenously borne microbes, toxins, or emboli. In dogs, laboratory rodents, and human beings, the hepatic (Kupffer cells), and splenic macrophages are the primary cells responsible for removing circulating bacteria and other particles from the blood. In contrast, the cell responsible for the removal of circulating particles, pathogenic bacteria, and endotoxin from the blood of ruminants, cats, pigs, and horses, is mainly the pulmonary intravascular macrophage, a distinct population of phagocytes normally residing within the pulmonary capillaries (Fig. 9-6). In pigs, 16% of the pulmonary capillary surface is lined by pulmonary intravascular macrophages. In ruminants, 95% of intravenously injected tracer particles or bacteria are rapidly phagocytosed by these intravascular macrophages. Recent studies showed that an abnormally

## Pathologic Basis of Veterinary Disease, 4th Edition

---

reduced number of Kupffer cells in diseased liver results in proliferation of pulmonary intravascular macrophages, even in animal species in which these phagocytic cells are normally absent from the lung.

9.1.8

### DEFENSE MECHANISMS AGAINST OXIDANT-INDUCED LUNG INJURY

Existing in an oxygen-rich environment and being the site of numerous metabolic reactions, the lungs also require an efficient defense mechanism against oxidant-induced cellular damage (oxidative stress). This form of damage is caused by inhaled oxidant gases (e.g., nitrogen dioxide, ozone, sulfur dioxide, tobacco smoke), and by xenobiotic toxic metabolites produced locally or by reaching the lungs via the blood stream (e.g., 3-methylindole and paraquat), or by free radicals (reactive oxygen species) released by phagocytic cells during inflammation. Oxygen and free radical scavengers, such as catalase, superoxide dismutase, and vitamin E, are largely responsible for protecting pulmonary cells against peroxidation. These scavengers are present in alveolar and bronchiolar epithelial cells and in the extracellular spaces of the lung.

In summary, the defense mechanisms are so effective in trapping, destroying, and removing bacteria that, under normal conditions, animals can be exposed to aerosols containing massive numbers of bacteria without any ill effects. If defense mechanisms are impaired, inhaled bacteria colonize and multiply in bronchi, bronchioles, and alveoli, and produce infection, which can result in fatal pneumonia. Similarly, when airborne and blood-borne pathogens, inhaled toxicants, or free radicals overwhelm the protective defense mechanisms, cells of the respiratory system are likely to be injured, often causing serious respiratory diseases.

9.1.9

### IMPAIRMENT OF DEFENSE MECHANISMS IN THE RESPIRATORY SYSTEM

For many years, factors such as stress, viral infections, and pulmonary edema have been implicated in predisposing human beings and animals to secondary bacterial pneumonia. There are many pathways by which the defense mechanisms can be impaired; only those relevant to veterinary species are discussed.

9.1.9.1

#### VIRAL INFECTIONS

Viral agents are notorious in predisposing human beings and animals to secondary bacterial pneumonias by what is known as viral-bacterial synergism. A good example of this synergistic effect of combined virus-bacterial infections is documented from epidemics of human beings with influenza virus in which the mortality rate was significantly increased from secondary bacterial pneumonia. The most common viruses incriminated in predisposing animals to secondary bacterial pneumonia include influenza virus in pigs and horses; bovine herpesvirus 1 (BHV-1), parainfluenza-3 (PI-3), and bovine respiratory syncytial virus (BRSV) in cattle; and canine distemper virus in dogs. The mechanism of the synergistic effect of viral-bacterial infections was previously believed to be the destruction of the mucociliary blanket and a concurrent reduction of mucociliary clearance, but in experimental studies, viral infections did not significantly reduce the physical removal of particles or bacteria out of the lungs. Now it is known that 5 to 7 days after a viral infection, the phagocytic function of pulmonary alveolar macrophages is notably impaired. Other mechanisms by which viruses impair defense mechanisms are multiple and remain poorly understood ([Box 9-3](#)). Immunization against viral infections in many cases prevents or reduces the synergistic effect of viruses and thus the incidence of secondary bacterial pneumonia.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.1.9.2

### TOXIC GASES

Certain gases also impair respiratory defense mechanisms, rendering animals more susceptible to secondary bacterial infections. For instance, hydrogen sulfide and ammonia, frequently encountered on farms—especially in buildings with poor ventilation—can impair pulmonary defense mechanisms and increase susceptibility to bacterial pneumonia. The effects of environmental pollutants on the defense mechanisms of human beings and animals living in crowded and polluted cities remain to be determined.

470

471

9.1.9.2.1

### Box 9-3 Postulated Mechanisms by Which Viruses May Impair the Defense Mechanisms of the Respiratory Tract

Changes in mucociliary clearance

Injured epithelium enhances attachment for bacteria

Enhanced bacterial attachment predisposes to colonization

Decreased mucociliary clearance prolongs resident time of bacteria favoring colonization

Injured epithelium prevent mucociliary clearance and physical removal of bacteria

Lack of secretory products facilitate further cell injury

Break down the antimicrobial barrier in mucus and cells ( $\beta$ -defensins and anionic peptides)

Ciliostasis caused by inflammation or by some pathogenic organism (mycoplasmas)

Dysfunction of pulmonary alveolar macrophages and lymphocytes

Consolidation of lung cause hypoxia resulting in decreased phagocytosis

Infected macrophages fail to release chemotactic factors for other cells

Infected macrophages fail to attach and ingest bacteria

Lysosomes become disoriented and fail to fuse with phagosome-containing bacteria

Intracellular killing or degradation is decreased because of biochemical dysfunction

Reduced cytokines and secretory products impair bacterial phagocytosis

Viral induced apoptosis of alveolar macrophages

Altered CD4 and CD8 lymphocytes

9.1.9.3

### IMMUNODEFICIENCY

Immunodeficiency disorders, whether acquired or congenital, are often associated with increased susceptibility to viral, bacterial, and protozoal pneumonias. For instance, human beings with acquired

## Pathologic Basis of Veterinary Disease, 4th Edition

---

immunodeficiency syndrome (AIDS) are notably susceptible to pneumonia caused by proliferation of *Pneumocystis carinii*. This ubiquitous organism, which under normal circumstances is not considered pathogenic, is also found in the pneumonic lungs of immunosuppressed pigs, foals, dogs, and rodents. Pigs infected with the porcine reproductive and respiratory syndrome (PRRS) virus frequently develop *Pneumocystis carinii* infection. Arabian foals born with combined immunodeficiency disease easily succumb to infectious diseases, particularly adenoviral pneumonia. Also, large doses of chemotherapeutic agents, such as steroids and alkylating agents, cause immunosuppression in dogs, cats, and other animals, increasing susceptibility to secondary bacterial infections.

9.1.9.4

### OTHER CONDITIONS THAT PREDISPOSE TO SECONDARY BACTERIAL PNEUMONIA

Uremia, endotoxemia, dehydration, starvation, hypoxia, acidosis, pulmonary edema, anesthesia, ciliary dyskinesia, and stress are only some of the many conditions that have been implicated in impairing respiratory defense mechanisms and consequently predisposing animals to develop secondary bacterial pneumonia. The mechanisms by which each of these factors suppresses pulmonary defenses are diverse and sometimes not well understood. For instance, hypoxia and pulmonary edema decrease phagocytic function of pulmonary alveolar macrophages and alter the production of surfactant by type II pneumonocytes. Dehydration is thought to increase the viscosity of mucus, reducing or stopping mucociliary movement. Anesthesia induces ciliostasis with concurrent loss of mucociliary function. Ciliary dyskinesia, an inherited defect in cilia, causes abnormal mucus transport; starvation, hypothermia, and stress can reduce humoral and cellular immune responses.

9.1.10

### EXAMINATION OF THE RESPIRATORY TRACT

9.1.10.1

#### POSTMORTEM

The respiratory tract should always be examined in a systematic fashion. To determine whether negative pressure is present in the thoracic cavity, the diaphragm is punctured through the abdominal cavity before the thoracic cavity has been opened. When the diaphragm is punctured in a fresh carcass, the loss of negative pressure in the thorax causes the diaphragmatic cupola to drop back caudally toward the abdominal cavity, and at the same time, it makes an audible sound caused by the inrush of air into the thorax. Lack of this movement may be an indication of advanced pneumothorax, pleural effusion, or the presence of noncollapsible lungs because of pulmonary edema, pneumonia, fibrosis, or emphysema. In carcasses that have been dead for a long time, pulmonary air and gas produced by saprophytic bacteria leak into the pleural cavity, reducing pressure and collapsing the lung.

The rib cage must be removed by cutting along the costosternal joints and along the neck of the ribs (close to the costovertebral joints) in such a way that pleural adhesions and abnormal thoracic contents can be observed and grossly quantified (e.g., 200 ml of clear, yellow fluid). The tongue, pharynx, esophagus, larynx, trachea, and thoracic viscera (lungs, heart, and thymus) should be removed as a unit (often called the pluck) and placed on the postmortem table.

471

The pharynx and esophagus are opened starting at the pharynx by a single cut with scissors along the dorsal midline and inspected for ulcers, foreign bodies, and neoplasms. The larynx and trachea must be examined by opening both along the dorsal midline from cranial to caudal ends and then extending the incision into the large bronchi of the caudal lung lobes. Normal tracheobronchial mucosa has a smooth and glistening

472

## Pathologic Basis of Veterinary Disease, 4th Edition

pearl-colored surface with empty lumina in airways. The presence of foamy fluid in airways indicates pulmonary edema. Feed particles may suggest aspiration; however, careful examination of the mucosa is required because aspiration of ingesta from stomach or rumen into the lungs commonly takes place at death or can be displaced into these areas when the carcass is moved.

The lungs should be examined before incision. Normal lungs have a pink color (Fig. 9-10). External changes include the presence of rib imprints on the pleural surface when lungs fail to collapse. In addition, the lungs should be inspected for changes in color and texture and distribution of lesions. Color changes can be various shades of red, indicating hypostatic congestion, hyperemia (acute pneumonia), and hemorrhage; dark blue collapsed lobules or areas are indicative of atelectasis; pale pink to white lungs indicate notable anemia, fibrosis, or emphysema; and uniformly or patchy yellow-brown lungs indicate chronic passive congestion and pulmonary fibrosis likely secondary to chronic heart failure. Lungs from exsanguinated animals are generally paler than the normal pink color because of reduced blood in the pulmonary tissue. A covering of yellowish material on the pleural surface indicates accumulation of fibrin. Because it is impossible to describe the texture of normal lungs, repeated palpation is required to understand the actual texture of a normal lung. Texture is determined by gently palpating the surface and parenchyma of the lungs. Normal texture can change to firm, hard, elastic (rubbery), or crepitus (with a crackling sound or feeling). For a detailed description of lung texture, see Classification of Pneumonias. Palpation of the lungs, which should be gentle, also permits detection of nonvisible nodules or abscesses in the parenchyma. Knowing the distribution of a lesion in the lungs also facilitates diagnosis because particular etiologic agents cause lesions with specific distribution. Distribution of lesions is generally described as focal, multifocal, locally extensive, or diffuse. According to their topography, pulmonary lesions can also be classified as cranioventral, dorsocaudal, and so on.

**Fig. 9-10 Normal lung, pig.** The lung parenchyma appears homogeneously pink. The pale pink appearance of these normal lungs is due to exsanguination. The appearance of normal unexsanguinated lungs is bright pink to red. (Courtesy Dr. A. López, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Postmortem reports must also contain an estimate of the extent of the pulmonary lesions, preferably expressed as a percentage of the volume of the lungs affected. For instance, a report may read “cranioventral consolidation involving 40% of the lungs.” If the lungs have focal lesions, a rough estimate of the number should also be included in the report. For instance, “numerous (approximately 25), small (1 to 2 cm in diameter), hard nodules were randomly distributed in all lung lobes.”

Two methods are used to examine the nasal structures. The first is making a midsagittal cut through the head and removing the nasal septum; the second is making several transverse sections of the nose at the level of the second premolar teeth. This latter method is preferred when examining pigs suspected of having atrophic rhinitis or animals suspected of having nasal neoplasms.

### 9.1.10.2 HISTOPATHOLOGY AND BIOPSIES

Microscopic examination of pulmonary tissue is routinely done in diagnostic laboratories. Samples of normal and abnormal lungs, along with other appropriate tissue, should always be submitted in 10% buffered-neutral formalin for histopathologic evaluation. Lung biopsy specimens are taken only sporadically because complications often outweigh the diagnostic value. However, the use of new techniques, such as endoscopic-directed biopsies, has notably reduced some of these complications. Biopsies of the lungs are recommended in cases of chronic persistent pulmonary disease unresponsive to treatment or intrathoracic masses of undetermined origin. Endoscopic-directed biopsies of the nasal and bronchial mucosa are routinely used in clinical practice and generally have a much better diagnostic value.

### 9.1.10.3 BRONCHOALVEOLAR LAVAGE AND TRACHEAL ASPIRATES

Two valuable diagnostic tools in human medicine, bronchoalveolar lavage (BAL) and tracheal aspirates, have in recent years become more widely used in veterinary clinical diagnosis of respiratory ailments in animals, particularly in horses, dogs, and cats. The basis of BAL is sampling to determine the cellular and biochemical composition of the lung in a live animal by infusing and retrieving sterile fluid via the trachea. BAL is done by inserting a tube directly through the larynx into a bronchus, or transtracheally by inserting a tube through a needle percutaneously into the cervical trachea. Microscopic examination of properly collected, stored, and processed samples may reveal many erythrocytes and siderophages in pulmonary hemorrhage or left side heart failure; inclusion bodies or syncytial cells in viral pneumonias; increased number of leukocytes in pulmonary inflammation; abundant mucus in asthma or equine heaves (chronic obstructive pulmonary disease [COPD]); presence of pulmonary pathogens, such as parasites, fungi and bacteria; or tumor cells in cases of pulmonary neoplasia.

472

473

## 9.2 DISEASES OF THE RESPIRATORY SYSTEM

### 9.2.1 NASAL CAVITY AND SINUS MUCOSA

#### 9.2.1.1 PATTERN OF INJURY AND HOST RESPONSE

The conducting portion of the respiratory system is lined by pseudostratified columnar ciliated epithelium (most of the nasal cavity, paranasal sinuses, part of the larynx, and all of the trachea and bronchi), olfactory epithelium (part of the nasal cavity, particularly ethmoidal conchae), and squamous epithelium (nasal

## Pathologic Basis of Veterinary Disease, 4th Edition

vestibulum and parts of the larynx). The pattern of injury, inflammation, and host response is characteristic for each of these three types of epithelium and independent of its anatomic location.

**Fig. 9-11 Normal and injured mucosa, nasal conchae, rats.** Normal ciliated epithelium composed of tall columnar cells with numerous cilia. Day 1. Nasal epithelium following exposure to air containing an irritant gas (hydrogen sulfide). Note detachment and exfoliation of ciliated cells, leaving a denuded basement membrane (*arrows*). This same type of lesion is seen in viral or mechanical injury to the mucosa of the conducting system. Two days after exposure, the basement membrane is lined by rapidly dividing preciliated cells, some of which exhibit mitotic activity (*arrow*). Ten days after injury, the nasal epithelium is completely repaired. H&E stain. (From López A, Prior M, Yong S et al: Am J Vet Res 49:1107-1111, 1988.)

Pseudostratified ciliated epithelium, which lines most of the nasal cavity and nasopharynx, part of the larynx, and all of the trachea and bronchi, is exquisitely sensitive to injury. When these cells are irreversibly injured, whether caused by a viral infection, trauma, or inhalation of toxic gases, ciliated cells swell, typically lose their attachment to underlying basement membrane, and rapidly exfoliate (Fig. 9-11). A transient and mild exudate of plasma proteins and neutrophils covers the ulcer. In the absence of complications or secondary bacterial infections, a specific type of progenitor cell known as “nonciliated secretory cells” that is normally present in the mucosa migrates and undergoes mitosis to cover the denuded basement membrane, eventually differentiating into new ciliated epithelial cells (Fig. 9-11). Cellular migration, proliferation, and attachment are regulated by locally released growth factors and extracellular matrix proteins, such as collagen, integrins, and fibronectin. The capacity of ciliated epithelium to repair itself is remarkably effective. For instance, complete restoration of an uncomplicated ulcer of the tracheal mucosa can be completed in only 10 days. This sequence of cell degeneration, exfoliation, ulceration, mitosis, and repair is typically present in many viral infections in which viruses replicate in nasal, tracheal, and bronchial epithelium. Examples of transient infections of this type include human colds (rhinoviruses), infectious bovine rhinotracheitis (bovine herpesvirus 1), feline rhinotracheitis (feline herpesvirus 1), and canine infectious tracheobronchitis (canine adenovirus 2 and canine parainfluenza-2).

473

474

If damage to the mucociliary blanket becomes chronic, goblet cell hyperplasia results in excessive mucus production (hypersecretion) and reduced mucociliary clearance, and when there is loss of basement membrane, repair is by fibrosis and granulation tissue (scarring). In the most severe cases, prolonged injury causes squamous metaplasia, which together with scarring is an impediment to mucociliary clearance. In laboratory rodents, hyperplastic and metaplastic changes, such as those seen in nasal polyps and squamous metaplasia, are considered a prelude to neoplasia.

The second type of epithelium lining the conducting system is the sensory olfactory epithelium, present in parts of the nasal mucosa, notably in the ethmoidal conchae. The patterns of degeneration, exfoliation, and inflammation in the olfactory epithelium are similar to those of the ciliated epithelium, except that olfactory epithelium has only limited capacity for regeneration. When olfactory epithelium has been irreversibly injured, olfactory cells swell, separate from adjacent sustentacular cells, and finally exfoliate into the nasal cavity. Once the underlying basement membrane of the olfactory epithelium is exposed, cytokines are released by leukocytes and endothelial cells, and inflammatory cells move into the affected area. When damage is extensive, ulcerated areas of olfactory mucosa are replaced by ciliated and goblet cells or squamous epithelium, or by fibrous tissue, all of which eventually cause reduction or loss of olfactory function (anosmia).

Squamous epithelium, located in the vestibular region of the nose (mucocutaneous junctions), is the third type of epithelium present in the nasal passages. Compared with ciliated and olfactory epithelia, nasal squamous epithelium is quite resistant to all forms of injury.

### 9.2.1.2

#### ANOMALIES OF THE NASAL CAVITY

Localized congenital anomalies of the nasal cavity are rare in domestic animals and are often merely part of a more extensive craniofacial deformity (e.g., cyclops) or a component of generalized malformation (e.g., chondrodysplasia). Congenital anomalies involving the nasal cavity and sinuses, such as choanal atresia, some types of chondrodysplasia, and osteopetrosis, are incompatible with life. Examples of nonfatal congenital anomalies include cystic nasal conchae, deviation of nasal septum, cleft upper lip (harelip, cheiloschisis), hypoplastic turbinates, and cleft palate (palatoschisis) (see [Fig. 7-1](#)). Bronchoaspiration and aspiration pneumonia are common sequelae to cleft palate. Nasal and paranasal sinus cysts are slowly growing and expansive lesions that mimic neoplasia and cause severe cranial deformations in horses. These large cysts presumably originate congenitally from dentigerous tissue. As in other organs or systems, it is extremely difficult to determine the actual cause (genetic versus congenital) of anomalies based on pathologic evaluation.

### 9.2.1.3

#### METABOLIC DISTURBANCES OF THE NASAL CAVITY

Metabolic disturbances affecting the nasal cavity and sinuses are also rare in domestic animals. Amyloidosis, the deposition of amyloid protein (fibrils with a  $\beta$ -pleated configuration) in various tissues, has been sporadically reported in the nasal cavity of horses and human beings. Microscopic lesions are similar to those seen in other organs and consist of a deposition of hyaline amyloid material in nasal mucosa that is confirmed by a histochemical stain, such as Congo red. Unlike amyloidoses in other organs of domestic animals where amyloid is generally of the reactive type (amyloid AA), equine nasal amyloidosis appears to be of the immunocytic type (amyloid AL). Affected horses with large amyloid masses have difficulty breathing, epistaxis, and reduced athletic performance; on clinical examination, large, firm nodules

## Pathologic Basis of Veterinary Disease, 4th Edition

---

resembling neoplasms (amyloidoma) can be observed in the alar folds, rostral nasal septum, and floor of nasal cavity.

### 9.2.1.4 CIRCULATORY DISTURBANCES OF THE NASAL CAVITY

#### 9.2.1.4.1 Congestion and Hyperemia

The nasal mucosa is well vascularized and is capable of rather dramatic variation in blood flow, whether passively a result of interference with venous return (congestion) or actively because of vasodilation (hyperemia). Congestion of the mucosal vessels is a nonspecific lesion commonly found at necropsy and presumably associated with the circulatory failure preceding death (e.g., heart failure, bloat in ruminants where the increased intraabdominal pressure causes increased intrathoracic pressure impeding the venous return from the head and neck). Hyperemia of the nasal mucosa is seen in early stages of inflammation, whether caused by irritations (e.g., ammonia, regurgitated feed), viral infections, secondary bacterial infections, allergy, or trauma.

474

#### 9.2.1.4.2 Hemorrhage

475

Epistaxis is the clinical term used to denote blood flow from the nose (nosebleed) regardless of whether blood originates from the nasal mucosa or from deep in the lungs. Unlike blood in the digestive tract, where the approximate anatomic location of the bleeding can be estimated by the color the blood imparts to fecal material, blood in the respiratory tract is always red. This fact is due to the rapid transport of blood out of the respiratory tract by the mucociliary blanket and during breathing. Hemorrhages into the nasal cavity can originate from local trauma, erosions of submucosal vessels by inflammation (e.g., guttural pouch mycosis), or neoplasms. Hemoptysis refers to the presence of blood in sputum or saliva (coughing or spitting blood), and it is most commonly the result of pneumonia, lung abscesses, ulcerative bronchitis, pulmonary thromboembolisms, and pulmonary neoplasia.

Ethmoidal (progressive) hematomas are important in older horses and are characterized clinically by chronic, progressive, often unilateral nasal bleeding. Grossly or endoscopically, an ethmoidal hematoma appears as a single, soft, tumorlike, pedunculated, expansive, dark red mass arising from the mucosa of the ethmoidal conchae ([Fig. 9-12](#)). Microscopic examination reveals a capsule lined by epithelium and hemorrhagic stromal tissue infiltrated with abundant macrophages, some of which are siderophages.

#### 9.2.1.5 INFLAMMATION OF THE NASAL CAVITY

Inflammation of the nasal mucosa is called rhinitis and that of the sinuses, sinusitis. These conditions usually occur together, although mild sinusitis can be undetected. Clinically, rhinosinusitis is characterized by nasal discharge.

**Fig. 9-12 Ethmoidal hematoma, midsagittal section of head, horse.** A large amount of dark-red hemorrhage overlying the ethmoid conchae conceals an underlying hematoma in these conchae. (Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University.)

The occurrence of infectious rhinitis presupposes an upset in the balance of the normal microbial flora of the nasal cavity. Innocuous bacteria present normally protect the host through a process called competitive exclusion, whereby potential pathogens are kept at harmless numbers. Disruption of this protective mechanism can be caused by respiratory viruses, pathogenic bacteria, fungi, irritant gases, environmental changes, immunosuppression, local trauma, stress, or prolonged antibacterial therapy.

Based on the nature of exudate, rhinitis can be classified as serous, catarrhal, purulent, fibrinous, or granulomatous. These types of inflammatory reactions can progress from one to another (i.e., serous to catarrhal to purulent), or in some instances exudates can be mixed, such as those seen in mucopurulent, fibrinohemorrhagic, or pyogranulomatous rhinitis. Microscopic examination of impression smears and bacterial or fungal cultures are generally required in establishing the cause of the exudate. Other results are hemorrhage, ulcers, and mucosal hyperplasia in inflamed nasal mucosa. Rhinitis also can be classified according to the age of the lesions as acute, subacute, or chronic; to the severity of the insult as mild, moderate, or severe; and to the etiologic agent as viral, allergic, bacterial, mycotic, traumatic, or toxic.

### 9.2.1.5.1

#### Serous Rhinitis

Serous rhinitis is the mildest form of inflammation and is characterized by hyperemia and increased production of a clear fluid locally manufactured by serous glands present in the nasal submucosa. Serous rhinitis is of clinical interest only. It is caused by mild irritants or cold air, and it occurs during the early stages of viral infections, such as the common cold in human beings and upper respiratory tract infections in animals, or in mild allergic reactions.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.1.5.2

### Catarrhal Rhinitis

Catarrhal rhinitis is a slightly more severe process and has, in addition to serous secretions, a substantial increase in mucus production by increased activity of goblet cells and mucous glands. A mucous exudate is a thick, translucent, or slightly turbid viscous fluid, sometimes containing a few exfoliated cells, leukocytes, and cellular debris. In chronic cases, catarrhal rhinitis is characterized microscopically by notable hyperplasia of goblet cells. As the inflammation becomes more severe, the mucus is infiltrated with neutrophils giving the exudate a cloudy mucopurulent appearance. This exudate is referred to as mucopurulent.

9.2.1.5.3

### Purulent (Suppurative) Rhinitis

This inflammation, characterized by a neutrophilic exudate, occurs when the nasal mucosa suffers a more severe injury that generally is accompanied by mucosal necrosis and secondary bacterial infection. Cytokines, leukotrienes, complement activation, and bacterial products cause exudation of leukocytes, especially neutrophils, which mix with nasal secretions including mucus. Grossly the exudate in suppurative rhinitis is thick and opaque, but it can vary from white to green to brown, depending on the types of bacteria and type of leukocytes (neutrophils or eosinophils) present in the exudate (Fig. 9-13). In severe cases, the nasal passages are completely blocked by the exudate. Microscopically, neutrophils can be seen in the submucosa and mucosa and form plaques of exudate on the mucosal surface. Neutrophils are commonly found attached to the vessels and between epithelial cells in their migration to the surface of the mucosa.

475

476

9.2.1.5.4

### Fibrinous Rhinitis

This reaction occurs when nasal injury causes a severe increase in vascular permeability, resulting in abundant exudation of plasma fibrinogen, which coagulates into fibrin. Grossly, fibrin appears like a yellow, tan, or gray rubbery mat on nasal mucosa. Fibrin accumulates on the surface and forms a distinct film of exudate sometimes referred to as pseudomembrane (Fig. 9-14). If this fibrinous exudate can be removed, leaving an intact underlying mucosa, it is termed a croupous or pseudodiphtheritic rhinitis. Conversely, if the pseudomembrane is difficult to remove and leaves an ulcerated mucosa, it is referred to as diphtheritic or fibrinonecrotic rhinitis. The term *diphtheritic* was derived from human diphtheria, which causes a severe and destructive inflammatory process of the nasal, tonsillar, pharyngeal and laryngeal mucosa. Microscopically the lesions include a perivascular edema with fibrin, a few neutrophils infiltrating the mucosa, and superficial plaques of exudate consisting of fibrin strands mixed with leukocytes and cellular debris covering a necrotic and ulcerated epithelium. Fungal infections, such as aspergillosis, can cause a severe fibrinonecrotizing rhinitis.

Fig. 9-13 **Suppurative rhinitis, midsagittal section of head, calf.** The nasal septum has been removed to expose nasal conchae. The nasal mucosa is covered by yellow-white purulent exudate. There is also a large, round ulcer in mucosa of the nasopharynx (*arrow*). (Courtesy Western College of Veterinary Medicine.)

The nasal mucosa is covered by diphtheritic yellow membranes consisting of fibrinonecrotic exudate. Removal of these fibrinous membranes reveals focal ulcers in the underlying mucosa. (Courtesy Dr. Scott McBurney, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.1.5.5

### Granulomatous Rhinitis

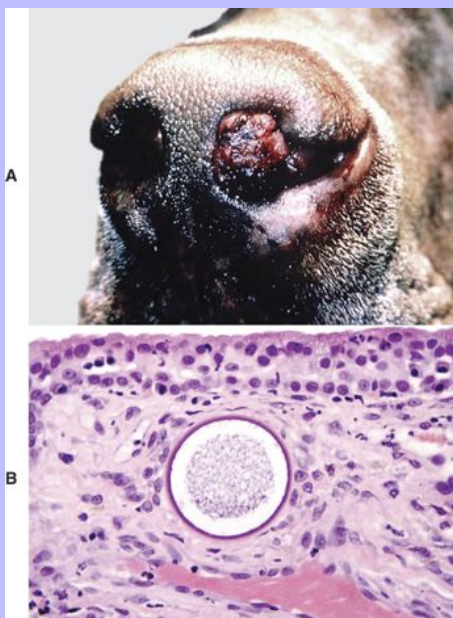

This reaction in the nasal mucosa and submucosa is characterized by infiltration of numerous activated macrophages mixed with few lymphocytes and plasma cells. In some cases, inflammation leads to the formation of polypoid nodules that, in severe cases, are large enough to cause obstruction of the nasal passages (Fig. 9-15). Granulomatous rhinitis is generally associated with chronic allergic inflammation or infection with specific organisms, such as those of systemic mycoses (see Lungs), tuberculosis, rhinosporidiosis, and with foreign bodies. In some cases, the cause of granulomatous rhinitis cannot be determined.

Inflammatory processes in the nasal cavity are not life threatening and usually resolve completely. However, some adverse sequelae in cases of infectious rhinitis include bronchoaspiration of exudate leading to bronchopneumonia. Chronic rhinitis often leads to destruction of the nasal conchae (turbinates), deviation of the septum, and eventually craniofacial deformation. Also, nasal inflammation may extend into the sinuses causing sinusitis, into facial bones causing osteomyelitis, through the cribriform plate causing meningitis, along the eustachian tubes causing otitis media and interna, and vestibular syndrome (abnormal head tilt and abnormal gait), which in severe cases may lead to emaciation.

476

477

King, College of Veterinary Medicine, Cornell University. B, Courtesy Dr. A. López, Atlantic Veterinary College.)**

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.1.5.6

### Sinusitis

Sinusitis occurs sporadically in domestic animals and is frequently combined with rhinitis (rhinosinusitis) or occurs as a sequela to penetrating or septic wounds of the cranium; improper dehorning in cattle, which exposes the frontal sinus; or tooth infection in horses and dogs (maxillary sinus). Based on the type of exudate, sinusitis are classified as serous, catarrhal, fibrinous (rare), purulent, and granulomatous (Fig. 9-16). Paranasal sinuses have poor drainage; therefore exudate tends to accumulate, causing mucocoele (accumulation of mucus), or empyema (accumulation of pus). Chronic sinusitis may extend into the adjacent bone (osteomyelitis) or through the ethmoidal conchae into the meninges and brain (meningitis and encephalitis).

9.2.1.6

### SPECIFIC DISEASES OF THE NASAL CAVITY AND SINUSES

9.2.1.6.1

#### Equine Nasal Diseases

9.2.1.6.1.1

#### Equine viral infections

Viruses such as equine viral rhinopneumonitis virus, influenza virus, adenovirus, and rhinovirus cause mild and generally transient respiratory infections in horses. The portal of entry for these respiratory viruses is typically aerogenous. All these infections are indistinguishable clinically; signs consist mainly of malaise, fever, coughing, and nasal discharge varying from serous to purulent. Viral respiratory infections are common medical problems in adult horses.

9.2.1.6.1.1.1

#### Equine viral rhinopneumonitis (EVR).

This disease, caused by two ubiquitous equine herpesvirus (EHV-1 and EHV-4), may be manifested as a mild respiratory disease in weanling foals and young racehorses or as abortion in mares. The portal of entry for the respiratory form is typically aerogenous and the disease is generally transient; thus, the primary viral-induced lesions in the nasal mucosa and lungs are rarely seen at necropsy unless complicated by secondary bacterial rhinitis, pharyngitis, or bronchopneumonia. Studies with polymerase chain reaction (PCR) techniques have demonstrated that, like other herpesvirus, EHV-1 and EHV-4 persist latently in the trigeminal ganglia for long periods of time. Reactivation because of stress or immunosuppression and subsequent shedding of the virus are the typical source of infection for susceptible animals on the farm.

9.2.1.6.1.1.2

#### Equine influenza.

This disease is a common, highly contagious, self-limiting upper respiratory infection of horses caused by aerogenous exposure to type A strains of influenza virus (A/equi-1 and A/equi-2). Equine influenza has high morbidity (outbreaks) but low mortality, and it is clinically characterized by fever, conjunctivitis, and serous nasal discharge. It occurs mainly in 2- to 3-year-old horses at the racetrack. As with human influenza, equine influenza is usually a mild disease, but occasionally it can cause severe bronchointerstitial pneumonia with pulmonary edema. In some horses, impaired defense mechanisms caused by the viral infection is complicated by a secondary bacterial bronchopneumonia caused by opportunistic organisms (*Streptococcus zooepidemicus*;

## Pathologic Basis of Veterinary Disease, 4th Edition

*Staphylococcus aureus*; *Bacteroides* sp.) found in the normal flora of the upper respiratory tract. Uncomplicated cases of equine influenza are rarely seen in the postmortem room.

9.2.1.6.1.1.3

### Other equine respiratory viruses.

Equine rhinovirus, adenovirus, and parainfluenza virus produce mild and transient upper respiratory infections (nasopharynx and trachea) in horses, unless complicated by secondary pathogens. In addition to reduced athletic performance, infected horses may have a temporary suppression of cell-mediated immunity leading to opportunistic infections, such as *Pneumocystis carinii* pneumonia. Fatal adenoviral infections with severe pneumonia or enteritis occur commonly in immunocompromised horses, particularly in Arabian foals with inherited combined immunodeficiency disease.

477

478

**Fig. 9-16 Fibrinonecrotic sinusitis, aspergillosis, dorsal section of nasal cavities, dog.** **A**, The nasal conchae have been destroyed by chronic granulomatous inflammation. ## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.1.6.1.2

### Equine bacterial infections: strangles, glanders, and melioidosis

Strangles, glanders, and melioidosis of horses are all systemic bacterial diseases that cause purulent rhinitis and suppuration in various organs. These diseases are grouped as upper respiratory diseases because nasal discharge is often the most notable clinical sign.

9.2.1.6.1.2.1

#### Strangles.

This infectious and highly contagious disease of Equidae is caused by *Streptococcus equi* ssp. *equi* (*Streptococcus equi*). It is characterized by suppurative rhinitis and lymphadenitis (mandibular and retropharyngeal) with occasional hematogenous dissemination to internal organs. Unlike *Streptococcus equi* ssp. *zooepidemicus* (*Streptococcus zooepidemicus*) and *Streptococcus dysgalactiae* ssp. *equisimilis* (*Streptococcus equisimilis*), *Streptococcus equi* is not part of the normal nasal flora. Infection occurs when susceptible horses come into contact with feed, exudate, or air droplets containing the bacterium. After penetrating through the nasopharyngeal mucosa, *Streptococcus equi* drains to the regional lymph nodes—mandibular and retropharyngeal lymph nodes—via lymphatic vessels. The gross lesions in horses with strangles (mucopurulent rhinitis) correlate with clinical findings and consist of copious amounts of mucopurulent exudate in the nasal passages with notable hyperemia of nasal mucosa. Affected lymph nodes are enlarged and contain thick purulent exudate (purulent lymphadenitis). The term “bastard strangles” is used in cases where hematogenous dissemination of *Streptococcus equi* results in metastatic abscesses in such organs as the lungs, liver, spleen, kidneys, brain, or in the joints. This form of strangles is often fatal.

Common sequelae to strangles include bronchopneumonia due to aspiration of nasopharyngeal exudate; laryngeal hemiplegia (“roaring”), resulting from compression of the recurrent laryngeal nerves by enlarged retropharyngeal lymph nodes; facial paralysis and Horner syndrome caused by compression of sympathetic nerves; and purpura hemorrhagica as a result of vasculitis caused by deposition of *Streptococcus equi* antigen-antibody complexes in arterioles, venules, and capillaries of the skin and mucosal membranes. In severe cases, nasal infection extends directly into the paranasal sinuses or to the guttural pouches via the eustachian tubes, causing inflammation and accumulation of pus (guttural pouch empyema). Rupture of abscesses in the mandibular and retropharyngeal lymph nodes leads to suppurative inflammation of adjacent subcutaneous tissue (cellulitis).

478

479

Strangles can affect horses of all ages, but it is most commonly seen in foals and young horses. It is clinically characterized by cough, nasal discharge, conjunctivitis, and painful swelling of regional lymph nodes. Some horses become carriers and a source of infection to other horses.

9.2.1.6.1.2.2

#### Glanders.

This infectious disease of Equidae is caused by *Burkholderia mallei* (*Pseudomonas mallei*) and can be transmitted to carnivores by consumption of infected horse meat. Human beings are also susceptible, and the untreated infection is often fatal. This bacterium has been listed as potential agent for biological warfare and bioterrorism. In the past, *Burkholderia mallei* was found throughout the world, but today glanders has been eradicated from most countries, except for some areas in North Africa, Asia, and Eastern Europe. There also have been some sporadic outbreaks reported in Brazil. The pathogenesis of glanders is not fully understood. Results from experimental infections

## Pathologic Basis of Veterinary Disease, 4th Edition

---

suggest that infection occurs via the ingestion of contaminated feed and water and, very rarely, via inhalation of infectious droplets. The portals of entry are presumed to be the oropharynx or intestine, where bacteria penetrate the mucosa and spread via lymph vessels to regional lymph nodes, then to the blood stream, and thus hematogenously to the internal organs, particularly the lungs.

Lesions in the nasal cavity start as pyogranulomatous nodules in the submucosa; these lesions subsequently ulcerate, releasing copious amounts of *Burkholderia mallei*-containing exudate into the nasal cavity. Finally, ulcerative lesions in conchal mucosa heal and are replaced by typical stellate (star-shaped), fibrous scars. In some cases the lungs also contain numerous gray, hard, small (2 to 10 mm), miliary nodules (resembling millet seeds), randomly distributed in one or more pulmonary lobes because of the hematogenous route. Microscopically, these nodules are typical chronic granulomas composed of a necrotic center, with or without calcification, surrounded by a thick band of connective tissue infiltrated with numerous macrophages, some giant cells, lymphocytes, and plasma cells. Cutaneous lesions, often referred to as equine farcy, are the result of severe suppurative lymphangitis characterized by nodular thickening of extended segments of lymph vessels in the subcutaneous tissue of the legs and ventral abdomen. Eventually affected lymph vessels rupture and release large amounts of purulent exudate through sinuses to the surface of the skin.

9.2.1.6.1.2.3

### Melioidosis (pseudoglanders).

This important, life-threatening disease of human beings, horses, cattle, sheep, goats, pigs, dogs, cats, and rodents is caused by *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*). This disease in horses is clinically and pathologically similar to glanders, hence the name *pseudoglanders*. In human beings, this infection can cause severe sepsis and septic shock, and has also been considered to have potential for biologic warfare. Melioidosis is currently present in Southeast Asia and, to a much lesser extent, in some European countries and Northern Australia, where the causative organism is frequently found in rodents, feces, soil, and water. Ingestion of contaminated feed and water appears to be the main route of infection; direct transmission between infected animals and insect bites has also been postulated as a possible mechanism of infection. After gaining entrance to the animal, *Burkholderia pseudomallei* is disseminated by the blood stream and causes suppuration and abscesses in most internal organs, such as nasal mucosa, joints, brain and spinal cord, liver, spleen, and lymph nodes. The exudate is creamy or caseous and yellow to green. The pulmonary lesions in melioidosis are those of an embolic bacterial pneumonia with formation of pulmonary abscesses. Focal adhesive pleuritis develops where abscesses rupture through the pleura and heal.

9.2.1.6.1.3

### Other causes of equine rhinitis

*Rhinosporidium seeberi* causes nasal infection in human beings, horses, mules, cattle, dogs, and cats. Gross lesions vary from barely visible granulomas to large expansive polypoid nodules that may be mistaken as tumors. These granulomatous nodules are detected by direct observation when present in the nasal mucosa close to the nares or by rhinoscopy when located into the deep nasal cavity. The offending organism, *Rhinosporidium seeberi*, is readily visible in histologic preparations and in impression smears, appearing as a large (400 µm), oval sporangium containing thousands of endospores (Fig. 9-15). *Rhinosporidium seeberi* used to be considered a mycotic agent, but recent phylogenetic investigations suggest that it is an aquatic protistan parasite of the class Mesosmycetozoea.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.1.6.2

### Bovine Nasal Diseases

9.2.1.6.2.1

#### Infectious bovine rhinotracheitis (IBR; “rednose”)

This disease is of great importance in the cattle industry because of the synergism of the IBR virus with *Mannheimia haemolytica* producing pneumonia. The causative agent, bovine herpesvirus 1 (BHV-1), has probably existed as a mild venereal disease in cattle in Europe since at least the mid-1800s, but the respiratory form was not reported until intensive management feedlot systems were first introduced in North America around the 1950s. Typically the disease is manifested as a transient, acute, febrile illness, which only in very severe cases results in inspiratory dyspnea caused by obstruction of airflow by exudate. Other forms of BHV-1 infection include ulcerative rumenitis, enteritis, and multifocal hepatitis in neonatal calves, nonsuppurative meningoencephalitis, infertility, and, in experimental infections, mastitis, mamillitis, and ovarian necrosis. Except for the encephalitic form, the type of disease caused by BHV-1 depends more on the site of entry than the viral strain. Like other herpesviruses, BHV-1 also can remain latent in nerve ganglia, with recrudescence following stress or immunosuppression. This virus also causes bovine abortion, systemic infections of calves, and genital infections, such as infectious pustular vulvovaginitis (IPV) and infectious balanoposthitis (IBP).

479

480

The respiratory form of IBR is characterized by severe hyperemia and focal necrosis of nasal, pharyngeal, laryngeal, tracheal (Figs. 9-14 and 9-17), and sometimes bronchial mucosa. As in other respiratory viral infections, IBR lesions are microscopically characterized by necrosis and exfoliation of ciliated cells followed by repair. Secondary bacterial infections of these areas of necrosis result in the formation of a thick layer of fibrinonecrotic material (diphtheritic) in the airway. Intracellular inclusion bodies, commonly seen in herpesvirus infections, are rarely seen in field cases because inclusion bodies occur only during the early stages of the disease.

**Fig. 9-17 Subacute fibrinous laryngitis and tracheitis, longitudinal (dorsal) section of larynx and trachea, calf.** Infectious bovine rhinotracheitis (IBR; bovine herpesvirus 1). **A**, Thick plaques of fibrinonecrotic exudate cover the laryngeal and tracheal mucosae. **B**, Note the intranuclear inclusion (*arrows*), characteristic of herpes virus infection, in a tracheal mucosal epithelial cell. Chronic inflammation is also present in the subjacent connective tissue. (**A**, Courtesy Dr. J.M. King, College of Veterinary Medicine, Cornell University. **B**, Courtesy College of Veterinary Medicine, University of Illinois.)

The most important sequela to IBR is pneumonia, which is caused either by direct aspiration of exudate from airways or as a result of an impairment in pulmonary defense mechanisms, thus predisposing the animal to secondary bacterial infection, most frequently *Mannheimia haemolytica* (see pneumonic manheimiosis discussion). Postmortem diagnosis of IBR is confirmed by isolation of the virus or its identification by immunohistochemistry or PCR.

### 9.2.1.6.2.2

#### Other bovine rhinitis

Nasal granulomas occur in cattle presumably as a result of repeated exposure to as yet unidentified inhaled antigens. Nasal granulomas (atopic rhinitis) are reported mainly in cattle in Australia, South Africa, and the United Kingdom, where affected cattle develop multiple, small, pink or red, polypoid nodules, starting in the nasal vestibule which in time, extend into the caudal aspect of the nasal septum.

## Pathologic Basis of Veterinary Disease, 4th Edition

These nodules are composed of fibrovascular tissue mixed with lymphocytes (granulation tissue) superficially lined by hyperplastic epithelium with abundant mast cells and eosinophils in the lamina propria (nasal eosinophilia). The microscopic features suggest that hypersensitivity type I (immediate), type III (immune complex), and IV (delayed) may be involved in nasal granulomas of cattle. Bovine (idiopathic) nasal granuloma must be differentiated from nasal mycetomas, nasal rhinosporidiosis, and nasal schistosomiasis, which also cause the formation of nodules in the nasal mucosa of cattle. An eosinophilic material consistent with the Splendore-Hoeppli phenomenon is occasionally observed in bovine mycotic granulomas. This phenomenon seen in some mycotic or bacterial infections is microscopically characterized by a deeply eosinophilic homogenous material surrounded by bacteria or mycelia. It is thought to result from a localized antigen-antibody response in tissue.

480

481

9.2.1.6.3

### Ovine and Caprine Nasal Disease

*Oestrus ovis* (Diptera: Oestridae; nasal bot) is the brownish fly, about the size of a honeybee that deposits its first-stage larvae in the nostrils of sheep in most parts of the world. Microscopic larvae mature into large bots (maggots), which spend most of their larval stages in nasal passages and sinuses, causing irritation, inflammation, and obstruction of airways. Matured larvae drop to the ground and pupate into flies. This type of parasitism in which living tissues are invaded by larvae of flies is known as myiasis (Fig. 9-18). Although *Oestrus ovis* is a primarily nasal myiasis of sheep, it sporadically affects goats, dogs, and sometimes human beings (shepherds). The presence of the larvae in nasal passages causes chronic irritation and erosive mucopurulent rhinitis and sinusitis; bots of *Oestrus ovis* can be found easily if the head is cut to expose the nasal passages. Rarely, larvae of *Oestrus ovis* penetrate the cranial vault through the ethmoidal plate, causing direct or secondary bacterial meningitis.

Infectious rhinitis is only sporadically reported in goats and most of these cases are caused by *Pasteurella multocida* or *Mannheimia haemolytica*. The lesions range from a mild serous to catarrhal or mucopurulent inflammation.

9.2.1.6.4

### Porcine Nasal Diseases

9.2.1.6.4.1

#### Inclusion body rhinitis

This disease of young pigs, with high morbidity and low mortality, is caused by a porcine cytomegalovirus (herpesvirus) and is characterized by a mild rhinitis. This virus commonly infects the nasal epithelium of piglets younger than 5 weeks. Because this disease is seldom fatal, lesions are seen only incidentally or in euthanized animals. In uncomplicated cases, the gross lesion is hyperemia of the nasal mucosa, but with secondary bacterial infections, mucopurulent exudate can be abundant. Microscopic lesions are typical and consist of a necrotizing, nonsuppurative rhinitis with giant, basophilic, intranuclear inclusion bodies in the nasal epithelium and glands (Fig. 9-19). Immunosuppressed piglets can develop a systemic cytomegalovirus infection characterized by necrosis of the liver, lungs, adrenal glands, and brain with intralesional inclusion bodies. Inclusion body rhinitis is clinically characterized by a mild and transient rhinitis, causing sneezing, nasal discharge, and excessive lacrimation.

Fig. 9-18 **Oestrus ovis, sheep.** **A**, Frontal sinus. Note the parasitic (fly) larvae in the frontal sinus (arrow). **B**, Nasal cavity. Close-up view of larvae of *Oestrus ovis* in a nasal cavity. (**A**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. **B**, Courtesy Drs. M. Sierra and J. King, College of Veterinary Medicine, Cornell University.)

9.2.1.6.4.2

### Atrophic rhinitis

A common worldwide disease of pigs, atrophic rhinitis (progressive atrophic rhinitis) is characterized by inflammation and atrophy of nasal conchae (turbinates). In severe cases, atrophy of the conchae may cause a striking facial deformity in growing pigs because of deviation of the nasal septum and nasal bones. The etiopathogenesis of atrophic rhinitis is complex and has been a matter of controversy for

## Pathologic Basis of Veterinary Disease, 4th Edition

many years. Pathogens historically associated with atrophic rhinitis include *Bordetella bronchiseptica*, *Pasteurella multocida*, *Haemophilus parasuis*, and viral infections such as porcine cytomegalovirus (inclusion body rhinitis). In addition, predisposing factors have included genetic makeup, environment, and nutritional deficiencies. The cause of atrophic rhinitis is currently believed to be a combined infection by specific strains of *Bordetella bronchiseptica* and toxigenic strains of *Pasteurella multocida* (types D and A). The only lesion associated with infection with *Bordetella bronchiseptica* alone is a mild to moderate turbinate atrophy, but this bacterium actively promotes the colonization of the nasal cavity by *Pasteurella multocida*. The toxigenic strains of *Pasteurella multocida* produce potent cytotoxins that inhibit osteoblastic activity and promote osteoclastic reabsorption in nasal bones, particularly in the ventral nasal conchae, where abnormal bone remodeling results in atrophy of conchae.

**Fig. 9-19 Inclusion body rhinitis caused by Cytomegalovirus infection, nasal conchae, 3-week-old pig.** Epithelial cells of nasal glands contain large basophilic intranuclear inclusion bodies (arrows). H&E stain. (Courtesy Dr. A. López, Atlantic Veterinary College.)

The degree of conchal atrophy in pigs with atrophic rhinitis varies considerably, and, in most pigs, the severity of the lesions does not correspond to the severity of the clinical signs. The best diagnostic method of evaluating this disease at necropsy is to make a transverse section of the snout between the first and second premolar teeth. In normal pigs, conchae are symmetric and fill most of the cavity, leaving only narrow air spaces (meatuses) between coiled conchae. The normal nasal septum is straight and divides the cavity into two mirror-imaged cavities. In contrast, the septum in pigs with atrophic rhinitis is generally deviated and the conchae appear smaller and asymmetric (Fig. 9-20). Conchal atrophy causes dorsal and ventral meatuses to appear rather enlarged, and in the most advanced cases, the entire nasal conchae may be missing, leaving a large, empty space.

Fig. 9-20 Atrophic rhinitis, transverse sections of nasal passages and sinuses, caudal surfaces, level of the first or second premolar teeth, pigs. *Top left:* Normal nasal cavity showing complete conchae (turbinates) that fill most of the nasal cavity and form narrow air passages (meatuses). *Top right:* Mild, symmetric atrophy of nasal conchae. *Bottom left:* Severe, unilateral atrophy of the right ventral nasal concha (\*) with deviation of the nasal septum to the left and widening of the ventral meatus. *Bottom right:* Severe, bilateral atrophy with complete loss of nasal conchae and extensive widening of the meatuses (\*). (Courtesy Dr. A. López, Atlantic Veterinary College.)

It may seem logical to assume that after loss of conchae in an obligate nasal breather, such as the pig, the filtration defense mechanism of the nasal cavity would be impaired, thus enhancing the chances of aerogenous infections in the lung. However, the relationship between atrophic rhinitis, pneumonia, and growth rates in pigs is still controversial.

Osteopenia of the conchae is the key microscopic lesion in atrophic rhinitis. Depending on the stage of the disease, mucopurulent exudate may be found on the surface of the conchae. Hyperplastic or metaplastic changes can occur in the nasal epithelium and glands, and infiltrates of lymphoplasmacytic cells can be present in the lamina propria. In summary, atrophic rhinitis is an important disease in pigs worldwide; morphologic diagnosis is simple, but additional understanding of the pathogenesis will be necessary before effective preventive measures can be established.

Atrophic rhinitis is clinically characterized by sneezing, coughing, and nasal discharge as a result of inflammation and atrophy of nasal conchae (turbinates). Obstruction of the nasolacrimal duct is common and results in accumulation of dust and dried lacrimal secretions on the skin inferior to the medial canthus of the eye.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.1.6.5

### Canine Nasal Diseases

Dogs have no specific viral infections affecting exclusively the nasal cavity or sinuses. Acute rhinitis occurs as part of general respiratory disease caused by several distinct viruses, such as canine distemper virus, canine adenovirus 1 and 2, canine parainfluenza virus, reovirus, and canine herpesvirus. The viral lesions in the respiratory tract are generally transient, but the effect of the virus on other tissues and cells can be fatal, as in distemper encephalitis in dogs. As in other species, secondary bacterial rhinitis, sinusitis, and pneumonia are possible sequelae of respiratory viral infections; *Bordetella bronchiseptica*, *Escherichia coli*, and *Pasteurella multocida* are the most common isolates in dogs with bacterial rhinitis. Immotile cilia syndrome (ciliary dyskinesia), a congenital disease, reduces mucociliary clearance and is an important factor in recurrent canine rhinosinusitis, bronchitis, bronchiectasis, and pneumonia.

482

483

9.2.1.6.5.1

### Other causes of canine rhinitis

*Aspergillus* spp. and *Penicillium* spp. cause mycotic rhinitis and sinusitis in dogs (canine nasal aspergillosis) (Fig. 9-16). Nasal biopsies reveal extensive necrosis of the nasal epithelium and thick plaques of fibrinopurulent exudate mixed with many fungal hyphae. *Cryptococcus neoformans* and *Rhinosporidium seeberi* infections of the nasal cavity occur sporadically in dogs (Fig. 9-15). Lesions are characterized by mucosal granulomas containing periodic acid–Schiff (PAS)-positive organisms, and the infection is clinically characterized by mucopurulent nasal discharge.

9.2.1.6.5.1.1

### Linguatula serrata.

This rare but highly specialized pentastomid parasite shares some morphologic features with arthropods and annelids and causes infection when dogs consume uncooked ruminant meat containing infective larvae. It occurs primarily in carnivores, although sheep and goats may become aberrant hosts. Human beings can also acquire the infection by ingesting raw ovine or caprine meat. The adult parasite is found throughout the nasal passages and sometimes can reach the sinuses and middle ear by moving through the exudate in the eustachian tubes. In common with other nasal parasites, *Linguatula serrata* acts as an irritant, causing sneezing, catarrhal inflammation, and epistaxis. The eggs of this parasite leave the host in the exudate, which is coughed up or swallowed and eliminated in the feces.

9.2.1.6.5.1.2

### Capillaria aerophila.

This nematode parasite is typically found in the trachea and bronchi of wild and domestic carnivores. In some cases, this parasite may involve the nasal passages and sinuses. Although generally asymptomatic, some dogs cough because of the local irritation caused by the parasites on the tracheal or bronchial mucosa.

The nasal cavity and sinuses of dogs can occasionally be infested with other parasites, including mites (*Pneumonyssus caninum*).

## Pathologic Basis of Veterinary Disease, 4th Edition

---

9.2.1.6.5.1.3

### Allergic rhinitis.

Allergic rhinitis (hay fever; nasolacrimal urticaria), which is so common in human beings sensitized and reexposed to inhaled pollens or allergens, has been reported only sporadically in dogs and cats. Hay fever in human beings and animals is a type I hypersensitivity reaction in which an IgE-mediated degranulation of mast cells results in an acute rhinitis and conjunctivitis. Microscopically the nasal mucosa is edematous and infiltrated with numerous eosinophils, neutrophils, and some macrophages. Clinically, allergic rhinitis is characterized by profuse serous nasal discharge and lacrimation.

9.2.1.6.6

### Feline Nasal Diseases

9.2.1.6.6.1

#### Feline viral rhinotracheitis (FVR)

This common and worldwide respiratory disease of cats is caused by a feline herpesvirus (FHV-1). The disease causes an impairment of pulmonary defense mechanisms, predisposing cats to secondary bacterial pneumonia. The virus also can remain latent in ganglia. The vast majority of cats that recover from FVR become carriers and shed FHV-1, either spontaneously or following stress. Susceptible animals, particularly kittens with low maternal immunity, become infected following exposure to a diseased or a carrier cat. Replication of FHV-1 in the nasal, conjunctival, pharyngeal, and to a lesser extent tracheal epithelium causes degeneration and exfoliation of cells.

Lesions caused by FHV-1 are fully reversible, but secondary infections with bacteria, such as *Pasteurella multocida*, *Bordetella bronchiseptica*, *Streptococcus* spp., and *Mycoplasma felis* can cause a chronic, severe suppurative rhinitis, and conjunctivitis. Intranuclear inclusion bodies are rarely seen in cats with FVR because inclusions are only present during the early stages of infection and have already disappeared by the time the cat is presented for diagnosis.

Respiratory sequelae to FVR can include chronic bacterial rhinitis and sinusitis with persistent purulent discharges; lysis of nasal bones, which can lead to conchal atrophy; permanent damage to the olfactory epithelium; and secondary bacterial pneumonia. In addition to rhinitis and interstitial pneumonia, FVR also causes ulcerative keratitis, hepatic necrosis, emaciation, abortion, and stillbirths. Clinical signs of FVR infection are characterized by lethargy, oculonasal discharges, severe rhinitis, and conjunctivitis.

9.2.1.6.6.2

#### Feline calicivirus (FCV)

This disease is caused by different strains of feline calicivirus. It is an important infection of the respiratory tract of cats, and depending on the virulence of the strain, lesions vary from a mild oculonasal discharge to severe rhinitis, mucopurulent conjunctivitis, and ulcerative gingivitis and stomatitis. The lesions, in addition to rhinitis and conjunctivitis, include acute, diffuse interstitial pneumonia with necrotizing bronchiolitis (see Pneumonias of Cats) and prominent ulcers of the tongue and hard palate. Primary viral lesions are generally transient, but secondary bacterial infections (*Bordetella bronchiseptica*; *Pasteurella multocida*; *Escherichia coli*) are a common complication. Some kittens develop lameness following infection or vaccination with calicivirus because of an acute and self-limiting arthritis ("limping kitten syndrome"). Carrier state and virus shedding from oronasal secretions and feces are natural sequelae following recovery from the acute phase of the disease.

483

484

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Clinical and pathologic features of FCV disease are strikingly similar, but not identical to those of FVR; these two viral infections account for 80% of all cases of feline respiratory diseases. A febrile hemorrhagic syndrome with high mortality (up to 50%) has been recently reported in cats infected with virulent strains of FCV.

9.2.1.6.6.3

### Feline chlamydiosis

This disease is a persistent respiratory infection of cats caused by *Chlamydophila felis*. Infection results in a conjunctivitis (similar to the conjunctivitis seen in human trachoma caused by *Chlamydia trachomatis*) and serous or mucopurulent rhinitis, but in severe cases, can also produce a mild, transient bronchointerstitial pneumonia referred to as feline pneumonitis (see Pneumonias of Cats).

9.2.1.6.6.4

### Other causes of feline rhinitis and sinusitis

9.2.1.6.6.4.1

#### *Mycoplasma felis*, feline leukemia virus, and feline immunodeficiency virus.

*Mycoplasma felis* can also cause mucopurulent conjunctivitis and a mild upper respiratory infection, with clinical signs and lesions overlapping those seen with chlamydiosis, FVR, and feline calicivirus infections. Respiratory infections and bronchopneumonia in cats may also be associated with the immunosuppressive effects of feline retroviruses, such as feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV).

9.2.1.6.6.4.2

#### Mycotic rhinitis.

The most common mycotic infection in the feline nasal cavity is caused by *Cryptococcus neoformans*. The lesions vary from discrete nasal granulomas to large masses of mucopurulent exudate filling the entire nasal cavity. Nasal aspergillosis and allergic rhinitis are sporadically reported in cats (see Other Causes of Canine Rhinitis).

9.2.1.7

### NEOPLASIA OF THE NASAL CAVITY AND PARANASAL SINUSES

Neoplasms of the nasal cavity and paranasal sinuses may arise from any of the tissues forming these structures, including bone (osteoma or osteosarcoma), cartilage (chondroma or chondrosarcoma), connective tissue (fibroma or fibrosarcoma, myxoma or myxosarcoma), blood vessels (hemangioma or hemangiosarcoma), and from all the different types of cells of glands and lining epithelium (adenoma, carcinoma or adenocarcinoma). Nasal tumors originating from stromal tissues, such as bone, cartilage, and connective tissue, are morphologically indistinguishable from those seen in other sites. In general, nasal neoplasms are rare in domestic animals, except for endemic ethmoidal neoplasms (retroviral) in sheep and cattle, which can occur in several animals in a flock or herd (see the following section).

In companion animals, nasal neoplasms are most common in dogs, particularly in breeds such as the collie, Airedale terrier, basset hound, and German shepherd. The cat and the horse are less frequently affected. The main sites in order of frequency are the nasal passages and sinuses for dogs, the tip of the nose (nasal planum; see [Chapter 17](#)) and nasal passages for cats, and the maxillary sinus and nasal passages for horses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

The majority of neoplasms in the nasal cavity are malignant. Benign nasal neoplasms (papilloma and adenoma) are rare and generally are either solitary or multiple, well-delineated nodules. In contrast, nasal carcinomas and nasal sarcomas are generally larger, but vary in size, and are often pale and multilobulated masses composed of fleshy to friable tissue (Fig. 9-21). Malignant neoplasms are locally invasive and tend to infiltrate sinuses, frontal brain, olfactory nerves, and vessels resulting in epistaxis. Carcinomas vary from anaplastic (poorly differentiated) to well differentiated, in which cell and tissue morphology retains some glandular (adenocarcinoma) or squamous cell patterns. Because nasal tumors in dogs and cats are usually large and invasive at the time of diagnosis, prognosis is usually poor and survival times are short. Sarcomas originating in the nasal cavity and paranasal sinuses are less common than carcinomas. Mesenchymal tumors can arise from bone (osteoma or osteosarcoma), cartilage (chondroma or chondrosarcoma), blood vessels (hemangioma or hemangiosarcoma), and connective tissue (fibroma or fibrosarcoma). Overall, benign epithelial and mesenchymal tumors are less common than their malignant counterparts. Secondary tumors in the nasal cavity are rare, with lymphoma being the most common metastatic tumor in the nasal cavity of domestic animals.

Nasal neoplasms become secondarily infected by bacteria, and clinical signs often overlap with those of infectious rhinitis and include catarrhal or mucopurulent nasal discharge, periodic hemorrhage, increased lacrimation as a result of obstruction of nasolacrimal ducts, and sneezing. In some instances, it is not possible to clinically or grossly differentiate neoplasms from hyperplastic nodules or granulomatous rhinitis. Some neoplasms may infiltrate adjacent bone structures and produce notable facial deformities, loss of teeth, exophthalmus, and nervous signs. Large neoplasms also project into the meatuses, narrow the lumen and interfere with airflow, causing stertorous breathing (Fig. 9-22). Biopsies, as well as brush and imprint cytology, have proven effective in the antemortem diagnosis of nasal neoplasms, particularly in those of epithelial lineage.

484

485

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.1.7.1

### Endemic Ethmoidal Tumors (Enzootic Nasal Tumors, Enzootic Intranasal Tumors, Enzootic Nasal Carcinoma)

A unique group of nasal carcinomas of sheep, goats, and cattle arise from the surface epithelium and glands of the ethmoidal conchae. These types of carcinomas are caused by an oncogenic retrovirus, and the neoplasm has been successfully transmitted to susceptible animals by inoculation of virus or infected tissues. Endemic ethmoidal tumors are typically invasive but do not metastasize (Fig. 9-23). In some regions of the world, ethmoid tumors have been reported in horses and pigs, particularly in those farms where the endemic nasal tumors of ruminants are known to occur.

**Fig. 9-22 Nasal adenocarcinoma, mid-sagittal section, head, adult dog.**

**A**, A large neoplastic mass (*arrows*) has arisen from the ethmoidal conchae and has infiltrated along the nasal passages. **B**, Multiple clusters of neoplastic epithelial cells with abundant eosinophilic cytoplasm and prominent nucleoli. ## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.1.7.2

### Nasal Polyps and Nasal Cysts Resembling Neoplasms

Nonneoplastic exophytic masses that resemble neoplasms are commonly found in horses, cats, and to a lesser extent other species. In horses, polyps tend to form in the ethmoidal region, whereas in cats, polyps are most frequently found in the nasopharynx and eustachian tubes. The pathogenesis of these benign growths is uncertain, although many cases follow chronic rhinitis or sinusitis. Grossly, polyps appear as firm, pedunculated nodules of various sizes protruding from the nasal mucosa into the nasal passages; the surface may be smooth, ulcerated, secondarily infected, and hemorrhagic. Microscopically, polyps are characterized by a core of well-vascularized stromal tissue that contains inflammatory cells and are covered by pseudostratified or squamous epithelium.

485

486

**Fig. 9-23 Nasal adenocarcinoma (arrows), midsagittal section of the head, sheep.** The tumor has occluded the right nasal passage and choanae. The location (ethmoturbinates) and type of tumor (carcinoma) are typical of retrovirus-induced “enzootic nasal carcinoma.” (Courtesy Dr. D.L. Craig, College of Veterinary Medicine, University of Tennessee.)

Nasal and paranasal sinus cysts are common in horses and are of great medical importance because they clinically mimic neoplasms or infections. Although not considered a neoplastic growth, cysts are expansive and cause deformation or destruction of the surrounding bone. These cysts are typically composed of an epithelial cell capsule filled with yellow or hemorrhagic fluid, and do not recur after surgical removal. Ethmoidal hematomas also resemble nasal tumors in horses.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 9.2.2 PHARYNX, GUTTURAL POUCHES, LARYNX, AND TRACHEA

#### 9.2.2.1 PATTERNS OF INJURY AND HOST RESPONSE

The laryngeal mucosa is formed by columnar ciliated epithelium with goblet cells (mucociliary blanket) and squamous epithelium, whereas the trachea is exclusively lined by columnar ciliated epithelium. The pattern of injury and host response in the larynx and trachea is similar to those in the nasal mucosa (see Defense Mechanisms of the Conducting System). The pharyngeal mucosa, composed of squamous epithelium, has similar patterns of necrosis and inflammation as the oral mucosa (see [Chapter 7](#)).

#### 9.2.2.2 ANOMALIES

Congenital anomalies of this region are rare in all species. Depending on their location and severity, they may be inconsistent with postnatal life, pose little or no problem, interfere with quality of life, or manifest themselves in later life. If clinical signs of respiratory distress, such as stridor, coughing, dyspnea, or gagging, do occur, they are usually exacerbated by excitement, heat, stress, or exercise.

##### 9.2.2.2.1 Brachycephalic Airway Syndrome

This clinical term refers to respiratory impairment caused by stenotic external nostrils and an excessive length of soft palate. These abnormalities are present in brachycephalic canine breeds, such as bulldogs, boxers, Boston terriers, pugs, Pekingese, and others. The defects are a result of a mismatch of the ratio of soft tissue to cranial bone and the obstruction of airflow by excessive length of the palatine soft tissue. Secondary changes, such as nasal and laryngeal edema caused by forceful inspiration, eventually lead to severe upper airway obstruction, respiratory distress, and exercise intolerance.

##### 9.2.2.2.2 Hypoplastic Epiglottitis, Epiglottic Entrapment, and Dorsal Displacement of the Soft Palate

These anomalies are important causes of respiratory problems and reduced athletic performance in horses. An undersized epiglottis is prone to entrapment below the arytenoepiglottic fold, causing an equine syndrome known as epiglottic entrapment. This syndrome also occurs in horses with lateral deviation and deformity of epiglottis, epiglottic cysts, or necrosis of the tip of the epiglottis. Hypoplastic epiglottis also occurs in pigs. Dorsal displacement of the soft palate, particularly during exercise, creates narrowing of the nasopharynx and abnormal air turbulence in the conducting system of horses. Epiglottic entrapment is clinically characterized by airway obstruction, exercise intolerance, respiratory noise, and cough.

##### 9.2.2.2.3 Subepiglottic and Pharyngeal Cysts

These types of anomalous lesions are occasionally seen in horses. These cysts vary in size (1 to 9 cm) and occur most commonly in the subepiglottic area and to a lesser extent in the dorsal pharynx, larynx, and soft palate. Cysts are lined by squamous or pseudostratified epithelium and contain thick mucus. Large cysts cause airway obstruction, reduced exercise tolerance, or dysphagia and predispose to bronchoaspiration of food.

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.2.2.4

### Tracheal Agenesis and Tracheal Hypoplasia

Tracheal hypoplasia occurs most often in English bulldogs and Boston terriers; the tracheal lumen is decreased throughout its length.

486

487

**Fig. 9-24 Tracheal collapse, trachea, pony.** *Left specimen:* The dorsal surface of the trachea is flattened dorsoventrally, the dorsal ends of the C-shaped tracheal rings are widely separated, and the dorsal ligament between the two ends is lengthened and thinned. *Right specimen (transverse section):* The ends of the tracheal rings are widely separated, and the dorsal wall of the trachea is formed by the lengthened and thinned dorsal ligament. (Courtesy Dr. C.S. Patton, College of Veterinary Medicine, University of Tennessee.)

9.2.2.2.5

### Tracheal Collapse and Tracheal Stenosis

Tracheal collapse with reduction in tracheal patency occurs in toy and miniature breeds of dogs, in which the condition is also called tracheobronchial collapse or central airway collapse. The defect also occurs in horses (Fig. 9-24), cattle, and goats. By radiographic, endoscopic, or gross examination, there is dorsoventral flattening of the trachea with concomitant widening of the dorsal tracheal membrane, which may then prolapse ventrally into the lumen. Most commonly, the defect extends the entire length of the trachea and only rarely affects the cervical portion alone. Affected segments with a reduced lumen contain froth and even are covered by a diphtheritic membrane. In horses, the so-called scabbard trachea is characterized by lateral flattening, so the tracheal lumen is a narrow vertical slit.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

Segmental tracheal collapse causing stenosis has been associated with congenital and acquired abnormalities. In severe cases, abnormal cartilaginous glycoproteins and loss of elasticity of tracheal rings causes the trachea to collapse. In some other cases, it is an acquired tracheal lesion that follows trauma, compression caused by extraluminal masses, peritracheal inflammation, and flawed tracheotomy or transtracheal aspirate techniques.

Other tracheal anomalies include tracheoesophageal fistula, which is most commonly found in human beings and sporadically in dogs and cattle. It can occur at any site of the cervical or thoracic segments of the trachea. Acquired tracheoesophageal fistula can be a complication of improper intubation, tracheotomy, or esophageal foreign body.

### 9.2.2.3 DEGENERATIVE DISEASES

#### 9.2.2.3.1 Laryngeal Hemiplegia (Paralysis)

This disease, sometimes called *roaring* in horses, is a common, but obscure, disease characterized by atrophy of the dorsal and lateral cricoarytenoid muscles (abductor and adductor of the arytenoid cartilage), particularly on the left side. Muscular atrophy is most commonly caused by a primary denervation (recurrent laryngeal neuropathy) of unknown cause (idiopathic axonopathy) and to a much lesser extent, secondary nerve damage. Idiopathic laryngeal hemiplegia is an incurable axonal disease (axonopathy) of the cranial laryngeal nerve that affects mostly larger horses. Secondary laryngeal hemiplegia is rare and occurs after nerve damage caused by other pathologic processes, such as compression or inflammation of the left recurrent laryngeal nerve. The medial retropharyngeal lymph nodes are located immediately ventral to the floor of the guttural pouches. As a result of this close anatomic relationship, swelling or inflammation of the guttural pouches and retropharyngeal lymph nodes often results in secondary damage to the laryngeal nerve. Common causes of secondary nerve damage (Wallerian degeneration) include guttural pouch mycosis, retropharyngeal abscesses, inflammation because of iatrogenic injection into the nerves, neck injury, and metastatic neoplasms involving the retropharyngeal lymph nodes (e.g., lymphosarcoma).

Grossly the affected laryngeal muscle in a horse with laryngeal hemiplegia is pale and smaller than normal (muscle atrophy) ([Fig. 9-25](#)). Microscopically, muscle fibers have lesions of denervation atrophy (see [Chapter 15](#)). Atrophy of laryngeal muscles also occurs in dogs as an inherited condition (Siberian husky and Bouvier des Flandres), as a degenerative neuropathy in older dogs, secondary to laryngeal trauma in all species (e.g., choke chain damage), or to hepatic encephalopathy in horses.

The abnormal inspiratory sounds (roaring) during exercise in horses with laryngeal hemiplegia are caused by paralysis of the left dorsal and lateral cricoarytenoid muscles, which cause incomplete dilation of the larynx, obstructing of airflow, and vibration of vocal cords.

### 9.2.2.4 CIRCULATORY DISTURBANCES

#### 9.2.2.4.1 Laryngeal and Tracheal Hemorrhages

Hemorrhages in these sites occur as mucosal petechiae and are most commonly seen in coagulopathies, inflammation, and sepsis, particularly in pigs with classical swine fever (hog cholera) or salmonellosis. Severe dyspnea and asphyxia before death can cause congestion, ecchymosis, and petechiae in the

487

488

## Pathologic Basis of Veterinary Disease, 4th Edition

laryngeal and tracheal mucosa; this lesion must be differentiated from postmortem imbibition of hemoglobin in autolyzed carcasses (see [Chapter 1](#)).

**Fig. 9-25 Laryngeal hemiplegia, larynx, dorsal surface, 2-year-old horse.** The left cricoarytenoideus dorsalis muscle is pale and atrophic (*arrows*), whereas the right cricoarytenoideus dorsalis muscle is normal. (*Courtesy Dr. A. López, Atlantic Veterinary College.*)

### 9.2.2.4.2

#### Laryngeal Edema

This lesion is a common feature of acute inflammation, but it is of particular importance because of its potential to obstruct the laryngeal orifice, resulting in asphyxiation. Laryngeal edema occurs in pigs with edema disease, in horses with purpura hemorrhagica, in cattle with acute interstitial pneumonia, in cats with systemic anaphylaxis, and in all species as a result of trauma, improper endotracheal tubing, inhalation of irritant gases (e.g., smoke), local inflammation, and allergic reactions. Grossly the laryngeal mucosa is thickened and swollen, often protrudes dorsally onto the epiglottis, and has a gelatinous appearance ([Fig. 9-26](#)).

### 9.2.2.4.3

#### Tracheal Edema

Also known as the “honker syndrome” or “tracheal edema syndrome of feeder cattle,” this entity is a poorly documented, acute disease of unknown cause, most often seen during the summer months. Severe edema and a few hemorrhages are present in the mucosa and submucosa of the dorsal surface of the

## Pathologic Basis of Veterinary Disease, 4th Edition

trachea, extending caudally from the midcervical area to as far as the tracheal bifurcation. On a cut section, the tracheal mucosa is diffusely thickened and gelatinous. Clinical signs include inspiratory dyspnea that can progress to oral breathing, recumbency, and death by asphyxiation in less than 24 hours.

**Fig. 9-26 Laryngeal edema, larynx, mature cow.** Note the edematous thickening of the laryngeal mucosa of the vocal cords, which can cause respiratory distress due to the narrowing of the laryngeal lumen (rima glottidis). (Courtesy Dr. J. Andrews, College of Veterinary Medicine, University of Illinois.)

### 9.2.2.5 INFLAMMATION

#### 9.2.2.5.1 Pharyngitis, Laryngitis, and Tracheitis

Inflammation of the pharynx, larynx, and trachea are important because of their potential to obstruct airflow and to lead to aspiration pneumonia. The pharynx is commonly affected by diseases of the upper respiratory and upper digestive tracts, and the trachea can be involved by extension from both the lungs and larynx.

Intraluminal foreign bodies in the pharynx, such as medicament boluses, apples, or potatoes, can obstruct the larynx and trachea. Also, pharyngeal obstruction can be caused by masses in surrounding tissue, such as neoplasms of the thyroid gland, thymus, and parathyroid glands.

#### 9.2.2.5.2 Pharyngeal Perforation

A number of nonspecific insults can cause lesions and clinical signs. Trauma may take the form of penetrating wounds in any species: perforation of the caudodorsal wall of the pharynx from the improper

## Pathologic Basis of Veterinary Disease, 4th Edition

use of drenching or balling guns in sheep, cattle, or pigs: choking injury because of use of collars in dogs	488
and cats; and the shearing forces of bite wounds. The results of the trauma may be minimal (local edema	489
and inflammation) or as serious as fatal exudate. Foreign bodies may be trapped anywhere in the	
pharyngeal region; the location and size determine the occurrence of dysphagia, regurgitation, dyspnea, or	
asphyxiation. Pigs have a unique structure known as the pharyngeal diverticulum (4 cm long in adult	
pigs), which is located in the pharyngeal wall rostral and dorsal to the esophageal entrance. It is important	
because barley awns may lodge in the diverticulum, causing an inflammatory swelling that affects	
swallowing. The diverticular wall may be perforated by awns or drenching syringes, which results in an	
exudate that can extend down the tissue planes between muscles of the neck and even into the	
mediastinum. The pharynx of the dog may also be damaged by trauma from chicken bones, sticks, and	
needles, resulting in the formation of a pharyngeal abscess.	

9.2.2.5.3

### Equine Pharyngeal Lymphoid Hyperplasia (Pharyngitis with Lymphoid Follicular Hyperplasia)

This lesion is a common cause of partial upper airway obstruction in horses, particularly in 2- and 3-year-old racehorses. Lymphoid hyperplasia is also seen in healthy horses as part of a response to chronic pharyngitis, which in many instances tends to regress with age in older animals. The cause is undetermined, but chronic bacterial infection combined with environmental factors may cause excessive antigenic stimulation and lymphoid hyperplasia. The gross lesions, visible endoscopically or at necropsy, consist of variably sized white foci located on the dorsolateral walls of the pharynx and extend into the openings of the guttural pouches and onto the soft palate. In severe cases, lesions may appear as pharyngeal polyps. Microscopically, the lesion is hyperplastic lymphoid nodules. Clinical signs consist of stertorous inspiration, expiration, or both.

9.2.2.5.4

### Inflammation of Guttural Pouches

The guttural pouches of horses are large diverticula (300 to 500 ml) of the ventral portion of the auditory (eustachian) tubes. These diverticula are therefore exposed to the same pathogens as is the pharynx and have drainage problems similar to those of sinuses. Although it is probable that various pathogens including viruses can infect them, the most common pathogens are fungi, which cause guttural pouch mycosis and guttural pouch empyema. Because of the close anatomic proximity of guttural pouches to the internal carotid arteries, cranial nerves (VI, IX, X, XI, and XII), and atlantooccipital joint, disease of these diverticula may involve these structures and cause a variety of clinical signs in horses.

Guttural pouch mycosis occurs primarily in stabled horses and is caused by *Aspergillus fumigatus* and other *Aspergillus* species. Infection is usually unilateral and presumably starts with the inhalation of spores from moldy hay. Grossly the mucosal surfaces of the dorsal and lateral walls of the guttural pouch mucosa are covered by a diphtheritic, fibrinonecrotic exudate. Microscopically the lesions are severe necrotic inflammation of the mucosa and submucosa with widespread vasculitis and intralesional fungal hyphae. The characteristic necrosis of this mycotic disease and its proximity to the internal carotid artery explain why guttural pouch mycosis can lead to vascular erosion with leakage of blood into the guttural pouch and epistaxis. Invasion of the internal carotid artery causes arteritis, which can also lead to formation of an aneurysm and fatal bleeding into the guttural pouches. In other cases, the fungi may be angioinvasive, leading to the release of mycotic emboli into the internal carotid artery, generally resulting in multiple cerebral infarcts. Dysphagia, another clinical sign seen in guttural pouch mycosis, is associated with damage to the pharyngeal branches of the vagus and glossopharyngeal nerves, which lie on the ventral aspect of the pouches. Horner's syndrome results from damage to the cranial cervical ganglion and

## Pathologic Basis of Veterinary Disease, 4th Edition

---

sympathetic fibers located in the caudodorsal aspect of the pouches. Finally, equine laryngeal paralysis (hemiplegia) can result from damage to the laryngeal nerves as previously described in Degenerative Disease, Laryngeal Hemiplegia (Paralysis).

Empyema of guttural pouches is a sequela to suppurative inflammation of the nasal cavities, most commonly from *Streptococcus equi* infection (strangles). In severe cases, the entire guttural pouch can be filled with purulent exudate (Fig. 9-27). The sequelae are similar to those of guttural pouch mycosis except that there is no erosion of the internal carotid artery. It is clinically characterized by nasal discharge, enlarged retropharyngeal lymph nodes, parotid swelling, dysphagia, and respiratory distress.

9.2.2.5.5

### Necrotic Laryngitis (Calf Diphtheria, Orolaryngeal Necrobacillosis)

Necrotic laryngitis is a common disease of feedlot cattle and cattle affected with other diseases, with nutritional deficiencies, or housed under unsanitary conditions. It also occurs in sheep. Necrotic laryngitis, caused by *Fusobacterium necrophorum*, is part of the syndrome termed orolaryngeal necrobacillosis, which can include lesions of the tongue, cheeks, palate, and pharynx. An opportunistic pathogen, *Fusobacterium necrophorum* produces several exotoxins and endotoxins after gaining entry either through lesions of viral infections, such as IBR and exudative stomatitis in cattle, or after traumatic injury produced by feed or careless use of specula or balling guns.

The gross lesions, regardless of location in the mouth or larynx (most common in the mucosa overlying the laryngeal cartilages), consist of well-demarcated, dry, yellow-gray, thick-crusts, fibrinonecrotic exudate (Fig. 9-28) that, in the early stages, is bounded by a zone of active hyperemia. Deep ulceration develops, and if the lesion does not result in death, healing is by granulation tissue formation.

Microscopically the necrotic foci are first surrounded by hyperemic borders, then by a band of leukocytes, and finally the ulcers heal by granulation tissue and collagen (fibrosis). The lesions can extend deep into the submucosal tissue. Numerous bacteria are evident at the advancing edge.

489

490

**Fig. 9-27 Guttural pouch empyema, guttural pouch, horse.** **A**, Note the swollen right neck (*outlined in yellow*) in this horse with guttural pouch empyema. **B**, The guttural pouch is filled with masses of inspissated purulent exudate (*arrow*). (**A**, Courtesy College of Veterinary Medicine, University of Illinois. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

There are numerous and important sequelae to calf diphtheria, the most serious being death because of toxemia or fusobacteremia. Sometimes the exudate may be copious enough to cause asphyxiation or be aspirated and cause bronchopneumonia. The clinical signs of necrotic laryngitis are fever, anorexia, depression, halitosis, moist painful cough, dysphagia, and inspiratory dyspnea and ventilatory failure because of fatigue of the respiratory muscles (diaphragm and intercostal).

**Fig. 9-28 Necrotic laryngitis, calf diphtheria (*Fusobacterium necrophorum*), larynx, calf.** Plaques of fibrinopurulent exudate are present on the mucosa of the arytenoid cartilages (*arrows*). Pieces of the exudate can be aspirated into the lungs and cause bronchopneumonia. (Courtesy Ontario Veterinary College.)

9.2.2.5.6

### Laryngeal Contact Ulcers

Ulcerative lesions in the larynx are commonly found in feedlot cattle. Grossly the laryngeal mucosa reveals circular ulcers (up to 1 cm in diameter), which may be unilateral or bilateral and sometimes deep enough to expose the underlying arytenoid cartilages. The cause has not been established, but causal agents such as viral, bacterial, and traumatic have been proposed along with increased frequency and rate of closure of the larynx (excessive swallowing and vocalization) when cattle are exposed to market and feedlot stresses, such as dust, pathogens, and interruption of feeding. Contact ulcers predispose a calf to diphtheria (*Fusobacterium necrophorum*) and laryngeal papillomas. Ulceration of the mucosa and necrosis of the laryngeal cartilages have also been described in calves, sheep, and horses under the term *laryngeal chondritis*. Laryngeal abscesses involving the mucosa and underlying cartilage occur as a herd or flock problem in calves and sheep, presumably caused by a secondary infection with *Arcanobacterium pyogenes* (*Actinomyces pyogenes*; *Corynebacterium pyogenes*).

9.2.2.5.7

### Tracheitis

The types of injury and host inflammatory responses in the trachea are essentially the same as those described for the nasal mucosa. Although tracheal mucosa is prone to aerogenous injury and necrosis, it has a remarkable capacity for repair. The most common causes of tracheitis are viral infections, such as those causing infectious bovine rhinotracheitis (IBR) (Fig. 9-17), equine virus rhinopneumonitis (EVR),

490

491

## Pathologic Basis of Veterinary Disease, 4th Edition

---

canine distemper, and feline rhinotracheitis. Viral lesions are generally mild and transient, but often become complicated with secondary bacterial infections.

Chemical tracheitis is also commonly seen following aspiration. Also, inhalation of fumes during barn fires can cause extensive injury and necrosis of the tracheal mucosa. In forensic cases, the presence of carbon pigment in the mucosal surface of trachea, bronchi, and bronchioles indicates that the burned animal was alive during the fire.

According to the exudate, tracheitis in all animal species is classified as catarrhal, purulent, fibrinous, or granulomatous. Chronic polypoid tracheitis occurs in dogs and cats, probably secondary to chronic infection.

### 9.2.2.5.7.1

#### Canine infectious tracheobronchitis (kennel cough)

This highly contagious infection is clinically characterized by an acute onset of coughing notably exacerbated by exercise. The term is nonspecific, much like “common cold” in human beings or “pneumonic manheimiosis” in cattle. The infection occurs commonly as a result of mixing dogs from different origins, such as occurs at commercial kennels, animal shelters, and veterinary clinics. Between bouts of coughing, most animals appear normal, although some have rhinitis, pharyngitis, tonsillitis, or conjunctivitis; and some with secondary pneumonia become quite ill.

The cause of canine infectious tracheobronchitis is complex, and many pathogens and environmental factors have been incriminated. *Bordetella bronchiseptica*, canine adenovirus 2 (CAV-2), and canine parainfluenza virus (CPV) are most commonly implicated. The severity of the disease is increased when more than one agent is involved or extreme environmental conditions (e.g., poor ventilation) add additional stresses. For example, dogs asymptotically infected with *Bordetella bronchiseptica* are more severely affected by superinfection with CAV-2 than those not carrying the bacterium. Other agents sometimes isolated but of lesser significance include CAV-1 (infectious canine hepatitis virus), reovirus type 1, canine herpesvirus, and *Mycoplasma* species.

Depending on the agents involved, gross and microscopic lesions are completely absent or they vary from catarrhal to mucopurulent tracheobronchitis, with enlargement of the tonsils and retropharyngeal and tracheobronchial lymph nodes. In dogs with *Bordetella bronchiseptica* infection, the lesions are suppurative or mucopurulent rhinitis and tracheobronchitis, and suppurative bronchiolitis. In contrast, when lesions are purely viral, microscopic changes are focal necrosis of the tracheobronchial epithelium. Sequelae can include spread either proximally or distally into the respiratory tract, the latter sometimes inducing chronic bronchitis and bronchopneumonia.

### 9.2.2.6

#### PARASITIC DISEASES OF THE LARYNX AND TRACHEA

Parasitic infections of the larynx and trachea can have dramatic obstructive consequences, but burdens sufficient to cause such effects are not commonly seen in veterinary practice.

### 9.2.2.6.1

#### Besnoitiosis (*Besnoitia bennetti*; *Besnoitia besnoiti*)

This apicomplexan coccidian parasite, whose life cycle is still unknown, can cause pedunculated lesions in the skin, sclera, nasal cavity, and larynx of horses and donkeys, cattle, and wild animals. Besnoitiosis has been reported from Africa, Central and South America, and Britain. Grossly, pale, round, exophytic

## Pathologic Basis of Veterinary Disease, 4th Edition

---

nodules up to 2 cm in diameter can be observed protruding from mucosal surfaces. These nodules microscopically consist of fingerlike projections covered by hyperplastic and sometimes, ulcerated epithelium containing numerous thick-walled parasitic cysts with little inflammatory response.

9.2.2.6.2

### Mammomonogamus laryngeus (*Syngamus laryngeus*)

This nematode is seen attached to the laryngeal mucosa of cattle in tropical Asia and South America, and cats (gapeworm) in the Caribbean and Southern United States. Occasionally, human beings with a persistent cough or asthmalike symptoms have the parasite in the larynx or bronchi.

9.2.2.6.3

### *Oslerus (Filaroides) osleri*

This parasite of dogs and other Canidae causes characteristic protruding nodules into the lumen at the tracheal bifurcation. They are readily seen on endoscopic examination or at necropsy. In severe cases, these nodules can extend 5 cm cranially or caudally from the tracheal bifurcation and even into primary and secondary bronchi. The disease occurs worldwide, and *Oslerus osleri* is considered the most common respiratory nematode of dogs.

The gross lesions are variably sized, up to 1 cm, submucosal nodules that extend up to 1 cm into the tracheal lumen (Fig. 9-29). Microscopically a mild mononuclear cell reaction is present when parasites are alive, but with the death of the parasite, an intense foreign body reaction develops with neutrophils and giant cells. Clinically, it can be asymptomatic, although it most often causes a chronic cough that can be exacerbated by exercise or excitement. Severe infestations can result in dyspnea, exercise intolerance, cyanosis, emaciation, and even death in young dogs.

491

Fig. 9-29 **Parasitic tracheobronchitis (*Oselrus osleri*), trachea and main bronchi, dog.** **A**, Note the numerous large parasitic nodules on the mucosal surface of the distal trachea and main bronchi. These nodules cause clinical signs only in severe infections. *Inset*: Filarial forms of *Oselrus osleri* can be seen in the nodule. **B**, Filarial forms of *Oselrus osleri* can be seen in the lamina propria of the tracheal mucosa. Numerous chronic inflammatory cells are also present. H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

### 9.2.2.7 NEOPLASMS OF GUTTURAL POUCHES, LARYNX, AND TRACHEA

#### 9.2.2.7.1 Neoplasms of the Guttural Pouches

These occur rarely in horses and are usually squamous cell carcinomas.

#### 9.2.2.7.2 Neoplasms of the Larynx and Trachea

Laryngeal neoplasms are rare in dogs and extremely so in other species, although they have been reported in cats and horses.

The most common laryngeal neoplasm in dogs is squamous cell carcinoma. Other less common tumors are laryngeal rhabdomyoma previously referred to as laryngeal oncocytoma, and chondromas and osteochondromas. Lymphoma involving the laryngeal tissue is sporadically seen in cats.

When large enough to be obstructive, neoplasms may cause a change or loss of voice, cough, or respiratory distress with cyanosis, collapse, and syncope. Other signs include dysphagia, anorexia, and exercise intolerance. The neoplasm is sometimes visible from the oral cavity and causes swelling of the neck. The prognosis is poor, as most lesions recur after excision.

Tracheal neoplasms are even more uncommon than those of the larynx. The tracheal cartilage or mucosa can be the site of an osteochondroma, leiomyoma, osteosarcoma, mast cell tumor, and carcinoma.

Lymphosarcomas in cats can extend from the mediastinum to involve the trachea.

### 9.2.3 LUNGS

#### 9.2.3.1 SPECIES DIFFERENCES

Each lung is subdivided into various numbers of pulmonary lobes. In the past, these were defined by anatomic fissures. However, in current anatomy, lobes are defined by the ramification of the bronchial tree. Following this criterion, the left lung of all domestic species is composed of cranial and caudal lobes, whereas the right lung, depending on species, is composed of cranial, middle (absent in horse), caudal, and accessory lobes. Each pulmonary lobe is further subdivided by connective tissue into pulmonary lobules, which in some species are rather prominent and in others are much less conspicuous. From a practical point of view, identification of the lungs among different species could be achieved by carefully observing the degree of lobation (external fissures) and the degree of lobulation (connective tissue between lobules). Cattle and pigs have well-lobated and well-lobulated lungs; sheep and goats have well-lobated but poorly lobulated lungs; horses have both poorly lobated and poorly lobulated lungs and resemble human lungs; finally, dogs and cats have well-lobated but not well-lobulated lungs. The degree of lobulation determines the degree of air movement between the lobules. In pigs and cattle, movement of air between lobules is practically absent because of the thick connective tissue wall separating individual lobules. This movement of air between lobules and between adjacent alveoli (pores of Kohn) constitutes what is referred to as collateral ventilation. This collateral ventilation is poor in cattle and pigs and good in dogs. The functional implications of collateral ventilation are discussed under Pulmonary Emphysema.

The lungs have an interconnecting network of stromal tissue supporting the blood and lymphatic vessels, nerves, bronchioles, and alveoli. For purposes of simplicity, the pulmonary interstitium can be anatomically divided into contiguous compartments: (1) bronchovascular interstitium, where main bronchi and pulmonary vessels are situated; (2) interlobular interstitium separating pulmonary lobules and supporting small blood and lymph vessels; and (3) alveolar interstitium supporting the alveolar walls that contain pulmonary capillaries and alveolar epithelial cells (no lymphatic vessels here) (see blood-air barrier discussion under Alveoli). Pulmonary changes, such as edema and emphysema, may affect one or more of these interstitial compartments.

### 9.2.3.2

#### CONGENITAL ANOMALIES

Congenital anomalies of the lungs are rare in all species but are most commonly reported in cattle and sheep. Compatibility with life largely depends on the type of structures involved and the proportion of functional tissue present at birth. Accessory lungs are one of the most common anomalies and consist of distinctively lobulated masses of incompletely differentiated pulmonary tissue present in the thorax, abdominal cavity, or subcutaneous tissue virtually anywhere in the trunk. Large accessory lungs can cause dystocia. Ciliary dyskinesia (immotile cilia syndrome; Kartagener's syndrome) is characterized by defective ciliary movement, which results in reduced mucociliary clearance because of a defect in the microtubules of all ciliated cells and, most importantly, in the ciliated respiratory epithelium and spermatozoa. Primary ciliary dyskinesia often associated with *situs inversus* has been reported in dogs, which as a result usually have chronic recurrent rhinosinusitis, pneumonia, and infertility. Pulmonary agenesis, pulmonary hypoplasia, abnormal lobulation, congenital emphysema, lung hamartoma, and congenital bronchiectasis are occasionally seen in domestic animals. Congenital melanosis is a common incidental finding in pigs and ruminants and is usually seen at slaughter (Fig. 9-30). It is characterized by black spots, often a few centimeters in diameter, in various organs, mainly the lungs, meninges, intima of the aorta, and caruncles of the uterus. Melanosis has no clinical significance, and the texture of pigmented lungs remains unchanged.

### 9.2.3.3

#### METABOLIC DISTURBANCES

#### 9.2.3.3.1

##### Pulmonary Calcification ("Calcinosis")

Calcification of the lungs occurs in some hypercalcemic states, generally secondary to hypervitaminosis D or from ingestion of toxic (hypercalcemic) plants, such as *Solanum malacoxylon* (Manchester wasting disease) that contain vitamin D analogs. It is also a common sequela to uremia and hyperadrenocorticism in dogs and to pulmonary necrosis (dystrophic calcification) in most species. Calcified lungs may fail to collapse when the thoracic cavity is opened and have a characteristic "gritty" texture (Fig. 9-31). Microscopically, lesions vary from calcification of the alveolar basement membranes (Fig. 9-31) to heterotopic ossification of the lungs. In most cases, pulmonary calcification in itself has little clinical significance, although its cause (e.g., uremia or vitamin D toxicosis) may be very important.

Fig. 9-30 **Pulmonary melanosis, lungs, pig.** Note the areas of black (melanin pigment) discoloration of the pleural surface. This pigmentation extends into the lungs and is an incidental finding that has no clinical or pathological significance. It is most common in “black-face” breeds. (Courtesy College of Veterinary Medicine, University of Illinois.)

### 9.2.3.4 ABNORMALITIES OF INFLATION

To achieve gaseous exchange, a balanced ratio of the volumes of air to capillary blood must be present in the lungs (ventilation/perfusion ratio), and the air and capillary blood must be in close proximity across the alveolar wall. A ventilation-perfusion mismatch occurs if pulmonary tissue is either collapsed (atelectasis) or overinflated (hyperinflation and emphysema).

#### 9.2.3.4.1 Atelectasis (Congenital and Acquired)

The term *atelectasis* means incomplete distention of alveoli and is used to describe lungs that have failed to expand with air at the time of birth (congenital atelectasis) or lungs that have collapsed after inflation has taken place (acquired atelectasis) (Figs. 9-32 and 9-33).

During fetal life, lungs are not fully distended, contain no air, and are partially filled with a locally produced fluid known as fetal lung fluid. Not surprisingly, lungs of aborted and stillborn fetuses sink when placed in water, whereas those from animals that have breathed float. At the time of birth, fetal lung

493

494

## Pathologic Basis of Veterinary Disease, 4th Edition

fluid is rapidly reabsorbed and replaced by inspired air, leading to the normal distention of alveoli. Congenital atelectasis occurs in newborns who fail to inflate their lungs after taking their first few breaths of air; it is caused by obstruction of airways, often as a result of aspiration of amniotic fluid and meconium (described under meconium aspiration syndrome) (Fig. 9-32). Congenital atelectasis also develops when alveoli cannot remain distended following initial aeration because of an alteration in quality and quantity of pulmonary surfactant produced by type II pneumonocytes and Clara cells. This form of congenital atelectasis is referred to in human neonatology as “acute respiratory distress syndrome” or as “hyaline membrane disease” because of the clinical and microscopic features of the disease. It commonly occurs in babies who are premature or born to diabetic or alcoholic mothers and is occasionally found in animals, particularly in foals and piglets. The pathetic, gasping attempts of affected foals and pigs to breathe have prompted the use of the name “barkers;” foals that survive may have brain damage from cerebral hypoxia (see Chapter 14) and are referred to as “wanderers,” owing to their aimless behavior and lack of a normal sense of fear.

**Fig. 9-31 Uremic pneumopathy from chronic renal failure, lung, 4-year-old dog.** The lungs have failed to collapse when the thorax was opened because of extensive mineralization of alveolar walls. *Inset:* Calcification of alveolar septa. Note the linear deposits of mineral in the alveolar septa (*arrows*). von Kossa stain with nuclear fast red counterstain. (*Figure and Inset*, Courtesy Dr. A. López, Atlantic Veterinary College.)

Fig. 9-32 **Multifocal neonatal atelectasis, lung, 1-day-old calf.**

Prominent mosaic pattern of normally inflated (*light*) and atelectatic, uninflated (*dark*) lobules. Atelectasis is due to aspiration of amniotic fluid, meconium, and squamous epithelial cells, causing obstruction of small bronchi and bronchioles at the time of birth. All pulmonary lobes are involved. Although focal lobular atelectasis is commonly seen in neonates, this lesion suggests that the fetus was acidotic and aspirated amniotic fluid. (From López A, Bildfell R: Vet Pathol 29:104-111, 1992.)

Fig. 9-33 **Schematic representation of the types of atelectasis. A,**

Normal alveolar distention. **B,** Obstructive atelectasis; obstruction of airways (i.e., exudate or parasite) affecting airflow and causing alveolar collapse. **C,** Compressive atelectasis; mass (i.e., abscess or tumor) compressing the lung parenchyma and causing alveolar collapse. (A, B, and C, Redrawn with permission from Dr. A. López, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Acquired atelectasis is much more common and occurs in two main forms: compressive and obstructive (Fig. 9-33). Compressive atelectasis has two main causes: space-occupying masses in the pleural cavity, such as abscesses and tumors, or from the transferred pressures, such as that caused by bloat, hydrothorax, hemothorax, chylothorax, and empyema (Fig. 9-34). Another form of compressive atelectasis occurs when the negative pressure in the thoracic cavity is lost because of pneumothorax. This form generally has massive atelectasis and thus is also referred to as lung collapse.

Obstructive (absorption) atelectasis occurs when there is a reduction in the diameter of the airways caused by mucosal edema and inflammation, or when the lumen of the airway is blocked by mucus plugs, exudate, aspirated foreign material, or lungworms (Fig. 9-33). When the obstruction is complete, trapped air in the lung eventually becomes reabsorbed. Unlike the compression type, obstructive atelectasis often has a lobular pattern as a result of blockage of the airway supplying that lobule. This lobular appearance of atelectasis is more common in species with poor collateral ventilation, such as cattle and sheep. The extent and location of obstructive atelectasis depends largely on the size of the affected airway (large versus small) and on the degree of obstruction (partial versus complete).

494

495

**Fig. 9-34 Atelectasis and hydrothorax, lungs, dog.** Atelectatic lung appears as dark depressed pulmonary tissues (*arrows*). Also note a large volume of transudate in the ventral pleural cavity (\*). (*Courtesy Atlantic Veterinary College.*)

Atelectasis also occurs when large animals are kept recumbent for prolonged periods, such as during anesthesia (hypostatic atelectasis). The factors contributing to hypostatic atelectasis are a combination of blood-air imbalance, shallow breathing, airway obstruction because of mucus and fluid that has not been drained from bronchioles and alveoli, and from inadequate local production of surfactant. Atelectasis can also be a sequel to paralysis of respiratory muscles and prolonged use of mechanical ventilation or general anesthesia in intensive care.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

In general, the lungs with atelectasis appear depressed below the surface of the normally inflated lung. The color is generally dark blue and the texture is flabby or firm; they are firm if there is concurrent edema or other processes, such as can occur in “shock” lungs (see Pulmonary Edema). Distribution and extent vary with the process, being patchy (multifocal) in congenital atelectasis, lobular in the obstructive type, and of various degrees in between in the compressive type. Microscopically the alveoli are collapsed or slitlike and the alveolar walls appear parallel and close together, giving prominence to the interstitial tissue even without any superimposed inflammation.

### 9.2.3.4.2

#### Pulmonary Emphysema

Pulmonary emphysema, often simply referred to as emphysema, is an extremely important primary disease in human beings, whereas in animals it is always a secondary condition resulting from a variety of pulmonary lesions. In human medicine, emphysema is strictly defined as an abnormal permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of alveolar walls (alveolar emphysema). This definition separates it from simple air space enlargement or hyperinflation, in which there is no destruction of alveolar walls and which can occur congenitally (Down syndrome) or be acquired with age (aging lung, sometimes misnamed “senile emphysema”). The pathogenesis of emphysema in human beings is still controversial, but current thinking overwhelmingly suggests that destruction of alveolar walls is largely the result of an imbalance between proteases released by phagocytes and antiproteases produced in the lung as a defense mechanism (the protease-antiprotease theory). The destructive process is markedly accelerated by any factor, such as cigarette smoking, pollution, or defects in the synthesis of antiproteases in human beings that increases the recruitment of macrophages and leukocytes in the lungs. This theory originated when it was found that human beings with homozygous  $\alpha_1$ -antitrypsin deficiency were remarkably susceptible to emphysema, and that proteases (elastase) inoculated intratracheally into the lungs of laboratory animals produced lesions similar to those found in the disease. More than 90% of the problem relates to cigarette smoking, and airway obstruction is no longer considered to play a major role in the pathogenesis of emphysema in human beings.

Primary emphysema does not occur in animals, and thus no animal disease should be called simply emphysema. In animals, this lesion is always secondary to obstruction of outflow of air or is agonal at slaughter. Secondary pulmonary emphysema occurs frequently in animals with bronchopneumonia, in which exudate plugging bronchi and bronchioles causes an airflow imbalance where the volume of air entering exceeds the volume leaving the lung. This airflow imbalance is often promoted by the so-called one-way valve effect caused by the exudate, which allows air into the lung during inspiration but prevents movement of air out of the lung during expiration.

Depending on the area of the lung affected, emphysema can be classified as alveolar or interstitial. Alveolar emphysema characterized by distention and rupture of the alveolar walls, forming variably sized air bubbles in pulmonary parenchyma, occurs in all species (Fig. 9-35). Interstitial emphysema occurs mainly in cattle, presumably because of their wide interlobular septa, and lack of collateral ventilation in these species does not permit air to move freely into adjacent pulmonary lobules. As a result, accumulated air penetrates the alveolar and bronchiolar walls and forces its way into the interlobular connective tissue, causing notable distention of the interlobular septa. It is also suspected that forced respiratory movements predispose to interstitial emphysema when air at high pressure breaks into the loose connective tissue of the interlobular septa (Fig. 9-35). Sometimes these bubbles of trapped air in alveolar or interstitial emphysema become confluent, forming large (several centimeters in diameter) pockets of air that are

495

496

## Pathologic Basis of Veterinary Disease, 4th Edition

referred to as bullae (singular: bulla); the lesion is then called bullous emphysema. This lesion is not a specific type of emphysema and does not indicate a different disease process, but rather is a larger accumulation of air at one focus. In the most severe cases, air moves from the interlobular septa into the connective tissue surrounding the main stem bronchi and major vessels (bronchovascular bundles), and from here air leaks into the mediastinum causing pneumomediastinum first, and eventually into the cervical and thoracic subcutaneous tissue causing subcutaneous emphysema.

**Fig. 9-35 Bovine pulmonary edema and emphysema (fog fever), lung, cow.** **A**, Emphysema, edema, and interstitial pneumonia involving all pulmonary lobes. Note the variably sized air bubbles in the interlobular septa and pulmonary parenchyma. The texture of these lungs would be notably crepitus due to the accumulation of air in pulmonary parenchyma. **B**, Note the thick eosinophilic hyaline membranes lining the alveoli. The alveoli are dilated and also contain some edema fluid, occasional pulmonary macrophages, and necrotic alveolar cells. H&E stain. ## Pathologic Basis of Veterinary Disease, 4th Edition

---

It should be noted that mild and even moderate alveolar emphysema is difficult to judge at necropsy and by light microscopy unless special techniques are used to prevent collapse of the lung when the thorax is opened. These techniques include plugging of the trachea or intratracheal perfusion of fixative (10% neutral-buffered formalin) before the thorax is opened to prevent collapse of the lungs. Important diseases that cause secondary pulmonary emphysema in animals include small airway obstruction (such as heaves) in horses and pulmonary edema and emphysema (fog fever) in cattle (Fig. 9-35) and exudates in bronchopneumonia.

9.2.3.5

### CIRCULATORY DISTURBANCES OF THE LUNGS

Lungs are extremely well-vascularized organs with a dual circulation provided by pulmonary and bronchial arteries. Disturbances in pulmonary circulation have a notable effect on gaseous exchange, which may result in life-threatening hypoxemia and acidosis. In addition, circulatory disturbances in the lungs can have an impact on other organs, such as the heart and liver. For example, impeded blood flow in the lungs because of chronic pulmonary disease results in cor pulmonale, which is caused by pulmonary hypertension followed by cardiac dilation, right heart failure, chronic passive congestion of the liver (nutmeg liver), and generalized edema (anasarca).

9.2.3.5.1

#### Hyperemia and Congestion

Hyperemia is an active process that is part of acute inflammation, whereas congestion is the passive process resulting from decreased outflow of venous blood, as occurs in congestive heart failure (Fig. 9-36). In the early acute stages of pneumonia, the lungs appear notably red, and microscopically, blood vessels and capillaries are engorged with blood from hyperemia. Pulmonary congestion is most frequently caused by heart failure, which results in stagnation of blood in pulmonary vessels, leading to edema and egression of erythrocytes into the alveolar spaces. As with any other foreign particle, erythrocytes in alveolar spaces are rapidly phagocytosed (erythrophagocytosis) by pulmonary/alveolar macrophages.

496

497

When extravasation of erythrocytes is severe, large numbers of macrophages with brown cytoplasm may accumulate in the bronchoalveolar spaces. The brown cytoplasm is the result of accumulation of considerable amounts of hemosiderin; these macrophages filled with iron pigment (siderophages) are generally referred to as heart failure cells (Fig. 9-37). The lungs of animals with chronic heart failure usually have a patchy red appearance with foci of brown discoloration because of accumulated hemosiderin. In severe and persistent cases of heart failure, the lungs fail to collapse because of edema and pulmonary fibrosis. Terminal pulmonary congestion (acute) is frequently seen in animals euthanized with barbiturates and should not be mistaken for an antemortem lesion.

**Fig. 9-36 Acute pulmonary congestion, lungs, dog.** The lung parenchyma is red because of congestion of pulmonary vasculature and alveolar capillaries. (Courtesy Dr. A. López, Atlantic Veterinary College.)

Hypostatic congestion is another form of pulmonary congestion that results from the effects of gravity and poor circulation on a highly vascularized tissue, such as the lung. This type of gravitational congestion is characterized by buildup of blood in the lower side of the lung of animals in lateral recumbency, particularly horses and cattle. The affected portions of the lung appear dark red and can have a firmer texture. In animals and particularly human beings that have been prostrated for extended periods of time, hypostatic congestion may be followed by hypostatic edema, and hypostatic pneumonia as edema interferes locally with the bacterial defense mechanisms.

### 9.2.3.5.2

#### Pulmonary Hemorrhage

Pulmonary hemorrhages can occur as a result of trauma, coagulopathies, pulmonary thromboembolism from jugular thrombosis or from embolisms of exudate from a hepatic abscess that has ruptured into the vena cava (cattle), disseminated intravascular coagulation, vasculitis, or sepsis. A gross finding that resembles pulmonary hemorrhage and often leads to an erroneous diagnosis is the aspiration of blood after the carotid arteries and trachea have been cut at the time of slaughter. Affected lungs have numerous, focal (1 to 10 mm) areas of red discoloration scattered randomly throughout the lungs.

**Fig. 9-37 Chronic congestion and edema, because of chronic heart failure (dilative cardiomyopathy), lungs, 5-year-old dog.** The lungs have failed to collapse (fibrosis) and have a mottled and brownish appearance (hemosiderosis). *Inset:* Microscopic view of alveoli. Large numbers of macrophages containing hemosiderin (heart failure cells) are present in alveoli. During heart failure, red blood cells gain access to alveoli where they are rapidly phagocytosed by pulmonary macrophages and the iron of the hemoglobin molecule is converted to hemosiderin. Hemosiderin gives a positive reaction for iron with the Prussian blue reaction. Prussian blue (iron) reaction with nuclear fast red counterstain. (*Figure and Inset*, Courtesy Dr. A. López, Atlantic Veterinary College.)

Rupture of a major pulmonary vessel with resulting massive hemorrhage occurs occasionally in cattle when a growing abscess in a lung invades and disrupts the wall of a major pulmonary artery or vein (Fig. 9-38). In most cases, animals die rapidly, often with spectacular hemoptysis, and on postmortem examination, bronchi are filled with blood (Fig. 9-38).

“Exercise-induced pulmonary hemorrhage” (EIPH) is a specific form of pulmonary hemorrhage in racehorses following exercise and clinically is characterized by epistaxis. Because only a small percentage of horses with bronchoscopic evidence of hemorrhage have clinical epistaxis, it is likely that EIPH goes undetected in many cases. The pathogenesis is still controversial, but current literature suggests laryngeal paralysis, bronchiolitis, extremely high pulmonary vascular pressures during exercise, alveolar hypoxia, and preexisting pulmonary injury as possible causes. EIPH is seldom fatal; postmortem lesions in the lungs of horses that have been affected with several episodes of hemorrhage are characterized by large

497

498

## Pathologic Basis of Veterinary Disease, 4th Edition

areas of dark brown discoloration, largely in the caudal lung lobes. Microscopically, lesions are alveolar hemorrhages, abundant alveolar macrophages containing hemosiderin (siderophages), and mild interstitial fibrosis.

**Fig. 9-38 Fatal pulmonary hemorrhage.** **A**, Schematic of an abscess (green) eroding the wall of a major pulmonary artery (red) and causing bleeding into the airways (blue). **B**, Cut surface of lung, cow. Major bronchi and the trachea are filled with clotted blood. This cow died unexpectedly, with severe respiratory distress and blood coming from the nose and mouth. A large abscess in the lung had eroded through the wall of a major pulmonary vessel. (A, Courtesy Dr. A. López, Atlantic Veterinary College. B, Courtesy Dr. R. Curtis, Atlantic Veterinary College.)

### Pulmonary Edema

In normal lungs, fluid from the vascular space slowly but continuously passes into the interstitial tissue where it is rapidly drained by the pulmonary and pleural lymphatic vessels. Recent investigations demonstrated that alveolar fluid clearance across the alveolar epithelium is also a major mechanism of fluid removal from the lung. Edema develops when the rate of fluid transudation from pulmonary vessels into interstitium or alveoli exceeds that of lymphatic and alveolar removal. Pulmonary edema can be physiologically classified as cardiogenic (hydrostatic; hemodynamic) and noncardiogenic (permeability) types.

Hydrostatic (cardiogenic) pulmonary edema develops when there is an elevated rate of fluid transudation because of increased hydrostatic pressure in the vascular compartment or decreased osmotic pressure in the blood. Once the lymph drainage has been overwhelmed, fluid accumulates in the perivascular spaces, causing distention of the bronchovascular bundles and alveolar interstitium, and eventually leaks into the alveolar spaces. Causes of hemodynamic pulmonary edema include congestive heart failure (increased hydrostatic pressure), iatrogenic fluid overload, disorders in which blood osmotic pressure is reduced, such as in the hypoalbuminemia seen in some hepatic diseases, nephritic syndrome, and protein-losing enteropathy. Hemodynamic pulmonary edema also occurs when lymph drainage is impaired and is generally secondary to neoplastic invasion of lymph vessels.

Permeability edema (inflammatory) occurs when there is excessive opening of endothelial gaps or damage to the blood-air barrier (endothelial cells or type I pneumocytes). This type of edema is an integral and early part of the inflammatory response, primarily because of the effect of inflammatory mediators, such as leukotrienes, platelet-activating factor, cytokines, and vasoactive amines released by neutrophils, macrophages, mast cells, lymphocytes, and endothelial cells. These inflammatory mediators increase the permeability of the blood-air barrier. In other cases, permeability edema results from direct damage to the endothelium and pneumocytes, allowing plasma fluids to move freely from the vascular space into the alveolar lumen (Fig. 9-39). Because type I pneumocytes are highly vulnerable to some pneumotropic viruses (influenza, BRSV), toxicants (NO<sub>2</sub>, SO<sub>2</sub>, H<sub>2</sub>S, 3-methylindole), and particularly to free radicals, it is not surprising that alveolar edema commonly accompanies many viral or toxic pulmonary diseases. A permeability edema also occurs when endothelial cells in the lung are injured by bacterial toxins (sepsis), disseminated intravascular coagulation (DIC), anaphylactic shock, milk allergy, paraquat toxicity, and adverse drug reactions.

The concentration of protein in edematous fluid is greater in permeability edema (exudate) than in hemodynamic edema (transudate); this difference has been used clinically in human medicine to differentiate one type of pulmonary edema from another. Microscopically, edema fluid tends to stain more intensely eosinophilic in lungs with inflammation or damage to the blood-air barrier, because of its higher protein concentration than the fluid of hydrostatic edema from heart failure.

498

499

**Fig. 9-39 Pulmonary edema, lung, rat.** Normal lung with alveoli filled with air (*top*) and lung with severe pulmonary edema characterized by transudation of protein-rich fluid (deeply eosinophilic) filling the alveoli and congested alveolar septa (*bottom*). H&E stain.  
(Courtesy Dr. A. López, Atlantic Veterinary College.)

Grossly the edematous lungs—independent of the cause—are wet and heavy (Fig. 9-40); the color varies depending on the degree of congestion or hemorrhage; and fluid may be present in the pleural cavity. If edema is severe, bronchi and trachea contain considerable amounts of foamy fluid, which originates from the mixing of edema fluid and air. On cut surfaces, the lung parenchyma oozes fluid like a wet sponge. In cattle and pigs, the lobular pattern becomes rather accentuated because of edematous distentions of lymphatic vessels in the interlobular septa (Fig. 9-40). Severe pulmonary edema may be impossible to differentiate from peracute pneumonia; this fact is not surprising because pulmonary edema occurs in the very early stages of inflammation. Careful observation of the lungs at the time of necropsy is critical because diagnosis of pulmonary edema cannot be reliably performed microscopically. This is due in part to the loss of the edema fluid from the lungs during fixation with 10% neutral-buffered formalin and in part to the fact that the fluid itself stains very poorly or not at all with eosin because of its low protein content (hemodynamic edema). A protein-rich (permeability) edema is easier to visualize microscopically because it is deeply eosinophilic in hematoxylin and eosin (H&E) stained sections (Fig. 9-39), particularly if a fixative—such as Zenker's solution, which precipitates protein—is used.

499

500

**Fig. 9-40 Pulmonary edema, lungs, pig.** **A**, The lungs are distended by edema fluid, which has resulted in rounded edges and edematous distention of the interlobular septa. **B**, The cut surface is wet and the interlobular septa are markedly distended with edema fluid. Lung lobules are also congested. (**A and B**, Courtesy College of Veterinary Medicine, University of Illinois.)

Acute (adult) respiratory distress syndrome (ARDS; shock lung) is an important condition in human beings characterized by pulmonary hypertension, intravascular aggregation of neutrophils in the lungs, diffuse alveolar damage, permeability edema, and formation of hyaline membranes, which are a mixture of plasma proteins, fibrin, surfactant, and cellular debris. The pathogenesis is complex and multifactorial but in general terms can be defined as diffuse alveolar damage that results from lesions in distant organs, from generalized systemic diseases, or from direct injury to the lung. Sepsis, major trauma, aspiration of gastric contents, extensive burns, and pancreatitis are some of the disease entities known to trigger ARDS. All these conditions provoke “hyperreactive macrophages” to directly or indirectly generate overwhelming amounts of cytokines (mainly TNF- $\alpha$ , interleukin [IL]-1, IL-6, and IL-8). Some of these cytokines prime neutrophils stationed in the lung capillaries to release enzymes and free radicals, thus causing diffuse endothelial and alveolar damage that culminates in a fulminating pulmonary edema. A syndrome analogous to ARDS occurs in domestic animals and explains why pulmonary edema is one of the most common lesions found in many animals dying of sepsis, toxemia, aspiration of gastric contents, and pancreatitis, for example.

Neurogenic pulmonary edema is another distinctive, but poorly understood form of lung edema in human beings that follows increased intracranial pressure (i.e., head injury, brain edema, brain tumors, or cerebral

## Pathologic Basis of Veterinary Disease, 4th Edition

hemorrhage). This type of pulmonary edema can be experimentally reproduced in laboratory animals by injecting fibrin into the fourth ventricle. It involves both hemodynamic and permeability pathways presumably from massive sympathetic stimulation and overwhelming release of catecholamines. Neurogenic pulmonary edema has sporadically been reported in animals with brain injury or severe seizures or following severe stress and excitement.

### 9.2.3.5.4

#### Pulmonary Embolisms

With its vast capillary bed and position in the circulation, the lungs act as a safety net to catch emboli before they reach the brain and other tissues. However, this positioning is often to its own detriment. The most common pulmonary emboli in domestic animals are thromboemboli, septic (bacterial) emboli, fat emboli, and tumor cell emboli.

Pulmonary thromboembolism generally originates from a thrombus present elsewhere in the venous circulation (Fig. 9-41). Fragments released inevitably reach the lungs and become trapped in the pulmonary vasculature (Fig. 9-41). Small sterile thromboemboli are generally of little clinical or pathologic significance because they can be rapidly degraded and disposed of by the fibrinolytic system. Parasites such as *Dirofilaria immitis* and *Angiostrongylus vasorum*, endocrinopathies such as hyperadrenocorticism and hypothyroidism, glomerulopathies, and hypercoagulable states can be responsible for pulmonary arterial thrombosis and pulmonary thromboembolism in dogs. Pieces of thrombi breaking free from a jugular vein thrombus can cause pulmonary thromboembolism. This outcome is particularly evident in animals undergoing long-term intravenous catheterization (Fig. 9-42).

**Fig. 9-41 Sources of pulmonary emboli.** Schematic diagram of pulmonary emboli (red dots) arising from: (1) rupture of a hepatic abscess into the caudal vena cava; (2) vegetative valvular endocarditis (tricuspid valve); and (3) jugular thrombosis. Pulmonary infarcts are rare and often of little clinical significance because of the lung's dual arterial circulation (i.e., pulmonary and bronchial arteries). (Redrawn with permission from Dr. A. López, Atlantic Veterinary College.)

## Pathologic Basis of Veterinary Disease, 4th Edition

Septic emboli, pieces of thrombi contaminated with bacteria or fungi and broken free from infected mural or valvular thrombi in the heart and vessels, eventually become entrapped in the pulmonary circulation. These emboli originate most commonly from bacterial endocarditis (right side) and jugular thrombophlebitis in all species, hepatic abscesses that have eroded and discharge their contents into the caudal vena cava in cattle, and septic arthritis and omphalitis in farm animals (Fig. 9-41). When present in large numbers, septic emboli may cause unexpected death because of massive pulmonary edema; survivors generally develop pulmonary arteritis and thrombosis and embolic (suppurative) pneumonia, which may lead to pulmonary abscesses.

Fat emboli can form after bone fractures or surgical interventions of bone. These are not as significant a problem in domestic animals as they are in human beings. Brain emboli (i.e., pieces of brain tissue) in the pulmonary vasculature reported in severe cases of head injury in human beings has recently been recognized in the bovine lung following pneumatic stunning at slaughter. Although obviously not important as an antemortem pulmonary lesion, brain emboli are intriguing as a potential risk for public health in bovine spongiform encephalopathy (BSE). Hepatic emboli formed by circulating pieces of fragmented liver occasionally become trapped in the pulmonary vasculature following severe trauma and hepatic rupture. Tumor emboli (e.g., osteosarcoma and hemangiosarcoma in dogs and uterine carcinoma in cattle) can be numerous and striking and the ultimate cause of death in malignant neoplasia. In experimental studies, cytokines released during pulmonary inflammation are chemotactic for tumor cells and promote pulmonary metastasis.

500

501

**Fig. 9-42 Jugular thrombophlebitis and pulmonary thromboembolism, jugular vein and lung cut surface, cow. Note that the pulmonary thromboembolus is not attached to the wall of the pulmonary artery. (A and B, Courtesy Dr. A. López, Atlantic Veterinary College.)**

## Pathologic Basis of Veterinary Disease, 4th Edition

9.2.3.5.5

### Pulmonary (Lung) Infarcts

Because of a dual arterial supply to the lung, pulmonary infarction is rare and generally asymptomatic. However, pulmonary infarcts can be readily caused when pulmonary thrombosis and embolism are superimposed on an already compromised pulmonary circulation, such as occurs in congestive heart failure. It also occurs in dogs with torsion of a lung lobe (Fig. 9-43). The gross features of infarcts vary considerably depending on the stage, and they can be red to black, swollen, firm, and cone or wedge shaped. In the early acute stage, microscopic lesions are severely hemorrhagic, and this is followed by necrosis. In 1 to 2 days, a border of inflammatory cells develops, and a few days later, a large number of siderophages are present in the necrotic lung. If sterile, pulmonary infarcts heal as fibrotic scars; if septic, an abscess may form surrounded by a thick fibrous capsule.

**Fig. 9-43 Lobe torsion, lung and heart, dog.** The right middle lung lobe is markedly congested and hemorrhagic from complete torsion. Although the right middle lobe is most frequently affected, other lobes can also rotate and undergo torsion. (Courtesy Dr. R. Fredrickson, College of Veterinary Medicine, University of Illinois.)

9.2.3.6

### PATTERNS OF INJURY AND HOST RESPONSE IN THE LUNGS

9.2.3.6.1

#### Bronchi

The patterns of necrosis, inflammation, and repair in intrapulmonary bronchi are similar to those previously described for the nasal and tracheal epithelium. In brief, injury to ciliated bronchial epithelium may result in degeneration, detachment, and exfoliation of necrotic cells. Under normal circumstances, cellular exfoliation is promptly followed by inflammation, mitosis, cell proliferation, cell differentiation, and finally by repair (Fig. 9-44). Depending on the type of exudate, bronchitis can be fibrinous, catarrhal, purulent, fibrinonecrotic (diphtheritic), and sometimes granulomatous. When epithelial injury becomes

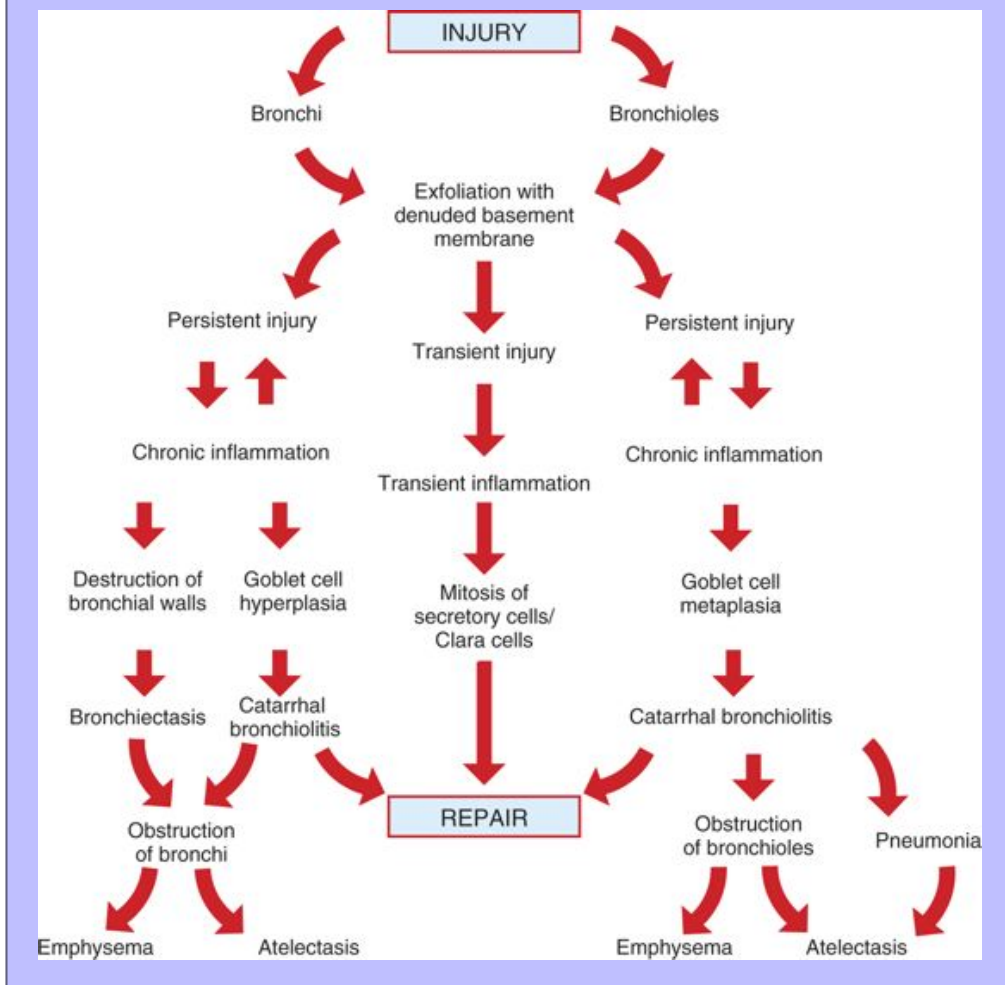

## Pathologic Basis of Veterinary Disease, 4th Edition

chronic, production of mucus is increased via goblet cell hyperplasia (chronic catarrhal inflammation). This form of chronic bronchitis is well illustrated in habitual smokers who continuously need to cough out excessive mucus secretions (sputum). Unfortunately, in some cases excessive mucus cannot be effectively cleared from airways, and this leads to chronic obstructive bronchitis (Fig. 9-45). Chronic bronchial irritation can also cause squamous metaplasia, in which highly functional but vulnerable ciliated epithelium is replaced by nonfunctional, but more resistant, squamous epithelium. Squamous metaplasia has a calamitous effect on pulmonary clearance because it causes a structural loss and functional breakdown in the mucociliary escalator.

501

502

Fig. 9-44 Schematic diagram of the patterns of host response and possible sequelae to bronchial and bronchiolar injury. (Redrawn with permission from Dr. A. López, Atlantic Veterinary College.)

Bronchiectasis is one of the most devastating sequela that follows chronic bronchitis. It consists of a pathologic and permanent dilation of a bronchus as a result of the accumulation of exudates in the lumen and partial rupture of bronchial walls. Destruction of walls occurs, in part, when proteolytic enzymes

## Pathologic Basis of Veterinary Disease, 4th Edition

released from phagocytic cells during chronic inflammation degrade and weaken the smooth muscle and cartilage that help to maintain normal bronchial diameter. Bronchiectasis may be saccular when destruction affects only a small localized portion of the bronchial wall or cylindrical when destruction involves a large segment of a bronchus. Grossly, bronchiectasis is manifested by prominent lumps in the lungs (bosselated appearance or having rounded eminences) resulting from distention of bronchi with exudate, which results in a concurrent obstructive atelectasis of surrounding parenchyma (Fig. 9-46). The cut surfaces of dilated bronchi are filled with purulent exudates; for this reason, bronchiectasis is often mistaken for pulmonary abscesses. Careful inspection, usually requiring microscopic examination, will confirm that exudate is contained and surrounded by remnants of a bronchial wall lined by squamous epithelium and not by a pyogenic membrane (connective tissue) as it is in the case of a pulmonary abscess. The squamous metaplasia further interferes with the normal function of the mucociliary escalator.

502

503

**Fig. 9-45** Chronic obstructive pulmonary disease (heaves), recurrent airway obstruction, goblet cell metaplasia, bronchiole, lung, horse. A, This horse had a 3-year history of recurrent dyspnea and terminal pulmonary emphysema. Numerous goblet cells (*arrows*) in the bronchiolar epithelium are discharging mucus (\*) into the lumen, causing complete obstruction of the bronchiole. The majority of the mucus has stained blue with alcian blue. Healthy bronchioles do not have goblet cells or mucus. PAS reaction–Alcian blue stain. B, Schematic diagram of goblet cell metaplasia in chronic obstructive pulmonary disease. Note how the mucus has obstructed the bronchiole. (*A and B, Courtesy Dr. A. López, Atlantic Veterinary College.*)

### Bronchioles

The epithelial lining of the bronchiolar region (transitional zone) is exquisitely susceptible to injury, particularly to that caused by some respiratory viruses (PI-3, adenovirus, BRSV, canine distemper), oxidant gases ( $\text{NO}_2$ ,  $\text{SO}_2$ ,  $\text{O}_3$ ), and toxic substances (3-methylindole). The precise explanation as to why bronchiolar epithelium is so prone to injury is still not clear, but it is presumably due in part to (1) its high vulnerability to oxidants and free radicals; (2) the presence of Clara cells rich in mixed-function oxidases, which locally generate toxic metabolites; and (3) the tendency for pulmonary alveolar macrophages and leukocytes to accumulate in this region of the lungs.

**Fig. 9-46 Severe bronchiectasis with chronic bronchopneumonia, right lung, calf.** **A**, Note the segmentally distended (bosselated) bronchi supplying the ventral portion of the cranial lung lobe. The lumens of affected bronchi are filled with purulent exudate. The surrounding lung parenchyma supplied by these bronchi is atelectatic (**C**). Bronchiectatic bronchi resemble pulmonary abscesses, but unlike abscesses, which are lined by a pyogenic membrane, the exudate in bronchiectasis is lined by the remnants of the bronchial wall. **B**, These distended bronchi are filled with purulent exudate. (**A**, Courtesy Ontario Veterinary College. **B**, Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee.)

Once injury to the cells becomes irreversible, bronchiolar ciliated cells degenerate and exfoliate into the bronchiolar lumen, leaving a denuded basement membrane. Repair in the bronchiolar region is similar to, but less effective than that in the tracheal or nasal mucosa. Under normal circumstances, recruited phagocytic cells remove exudate and cell debris from the lumina of affected bronchioles, thus preparing the basement membrane to be repopulated with new, undifferentiated cells originating from a rapidly dividing pool of Clara cells. After several days, these proliferating cells fully differentiate into normal bronchiolar ciliated cells (Fig. 9-44).

503

504

Depending on the types of injury and inflammatory response, bronchiolitis is classified as necrotizing, suppurative, catarrhal (mucous metaplasia), or granulomatous. In severe injury, exudate cannot be removed from the basement membrane of bronchioles. The exudate becomes infiltrated by fibroblasts, which form small masses of fibrovascular tissue and develop into well-organized, microscopic polyps inside the bronchiolar lumen. Their external surface eventually becomes covered by ciliated cells. This lesion is referred to as bronchiolitis obliterans and the polyps may become so large as to cause severe interference in airflow. Peribronchiolar proliferation of lymphocytes (BAL hyperplasia) is also a common microscopic lesion seen in chronic bronchiolitis.

On the other hand, if bronchiolar injury is mild but persistent, goblet cells normally absent from bronchioles proliferate from basal cells, resulting in goblet cell metaplasia and causing a profound alteration in the physicochemical properties of bronchiolar secretions (Fig. 9-45). The normally serous bronchiolar fluid released by Clara cells becomes a tenacious material when mucus produced by goblet cells is added. As a result of increased viscoelasticity of the mucus, bronchiolar secretions cannot be removed effectively by ciliary action, leading to plugging and obstruction of distal airways. Under such conditions, often grouped as chronic obstructive pulmonary disease, coughing is required to clear mucus from obstructed bronchioles. Pulmonary emphysema and atelectasis are further sequelae to bronchiolar metaplasia and mucous hypersecretion blocking or partially blocking the lumens of these bronchioles. These two inflation abnormalities are characteristically present in chronic obstructive pulmonary disease (COPD), such as “heaves” in horses.

COPD of horses (heaves, recurrent airway obstruction, chronic bronchiolitis-emphysema complex, chronic small airway disease, alveolar emphysema, and “broken wind”) is a common clinically asthmalike syndrome of horses and ponies, characterized by recurrent respiratory distress, chronic cough, poor athletic performance, airway neutrophilia, and mucus hypersecretion. The pathogenesis is still obscure, but genetic predisposition, T<sub>H</sub>2 (allergic) immune response, and the exceptional sensitivity of airways to environmental allergens (hyperreactive airway disease) have been postulated as the basic underlying mechanisms. What makes small airways hyperreactive to allergens is still a matter of controversy. Epidemiologic and experimental studies suggest that it could be the result of preceding bronchiolar damage caused by viral infections, ingestion of pneumotoxins (3-methylindole), or prolonged exposure to organic dust, endotoxin, and environmental allergens (molds). Most recently, it has been postulated that sustained inhalation of dust particles, whether antigenic or not, up-regulates the production of cytokines (TNF- $\alpha$ , IL-8, and monokine-inducible protein [MIP-2]) by alveolar macrophages, attracting neutrophils into the bronchioloalveolar region and promoting leukocyte-induced bronchiolar injury.

The lungs of horses with heaves are grossly unremarkable, except for extreme cases in which alveolar emphysema may be present. Microscopically the lesions include goblet cell metaplasia in bronchioles; plugging of bronchioles with mucus mixed with a few eosinophils (Fig. 9-45); peribronchiolar infiltration with lymphocytes, plasma cells, and variable numbers of eosinophils; and hypertrophy of smooth muscle in bronchi and bronchioles. In severe cases, accumulation of mucus leads to the complete obstruction of

## Pathologic Basis of Veterinary Disease, 4th Edition

bronchioles and alveoli, and resultant alveolar emphysema characterized by enlarged “alveoli” from the destruction of alveolar walls.

“Airway hyperresponsiveness” (hyperreactive airway disease) is another sequela of bronchiolar injury. It develops in human beings and animals (experimentally) following a transient and often innocuous viral infection of the lower respiratory tract or from exposure to certain allergens. Experimental work has shown that airway hyperreactivity in postviral bronchiolitis is associated with increased expression of Toll-like receptors and unusual susceptibility to inhaled endotoxin. Hyperreactive animals typically have an increased number of mast cells, eosinophils, and T lymphocytes in the airway mucosa. Clinically, airway hyperresponsiveness is characterized by an exaggerated bronchoconstriction following exposure to mild stimuli, such as cold air, or after animals are exposed to aerosols of histamine or methacholine.

9.2.3.6.2.1

### Feline asthma (feline asthma syndrome; feline allergic bronchitis)

Feline asthma, also known as feline allergic bronchitis, is a clinical syndrome in cats of any age characterized by recurrent episodes of bronchoconstriction, cough, or dyspnea. The pathogenesis is not well understood, but is presumed to originate, as in human asthma, as a type I hypersensitivity (IgE–mast cell reaction) to inhaled allergens. Dust, cigarette smoke, plant and household materials, and parasitic proteins have been incriminated as possible allergens. This self-limited allergic disease responds well to steroid therapy; thus it is rarely implicated as a primary cause of death except when suppressed defense mechanisms result in secondary bacterial pneumonia. Bronchial biopsies from affected cats at the early stages reveal mild to moderate inflammation characterized by mucosal edema and infiltration of leukocytes, particularly eosinophils. Increased numbers of circulating eosinophil leukocytes (blood eosinophilia) are present in some, but not all, cats with feline asthma. In the most advanced cases, chronic bronchoconstriction and excess mucus production may result in smooth muscle hyperplasia and obstruction of the bronchi and bronchioles, and infiltration of the airway mucosa by eosinophils. A syndrome known as canine asthma has been reported in dogs but is not as well characterized as the feline counterpart.

504

505

9.2.3.6.3

### Alveoli

Because of their extremely delicate structure, alveoli are quite vulnerable to injury once defense mechanisms have been overwhelmed. The alveolar wall is thin and has three layers composed of vascular endothelium, basal lamina (alveolar interstitium), and alveolar epithelium. These three layers of the alveolar septum constitute what is customarily referred to as the blood-air barrier (Fig 9-6). The epithelial side of the alveolus is primarily lined by rather thin type I pneumonocytes, which are arranged as a very delicate continuous membrane extending along the alveolar surface (Fig. 9-6). Type I pneumonocytes are particularly susceptible to noxious agents that reach the alveolar region either aerogenously or hematogenously. Injury from type I pneumonocytes causes swelling and vacuolation of these cells. When cellular damage has become irreversible, type I cells detach, resulting in denudation of the basement membrane, increased alveolar permeability, and alveolar edema. Alveolar repair is possible as long as the basement membrane remains intact and lesions are not complicated by further injury or infection. Within 3 days, cuboidal type II (granular) pneumonocytes, which are the precursor cells and more resistant to injury, undergo mitosis and provide a large pool of new undifferentiated cells. These new cells repave the denuded alveolar basement membrane and finally differentiate in type I pneumonocytes. When alveolar injury is diffuse, proliferation of type II pneumonocytes becomes so spectacular that the microscopic appearance of the alveolus resembles that of a gland or fetal lung; the lesion has been termed epithelialization or fetalization. Although it is part of the normal alveolar repair, hyperplasia of type II

## Pathologic Basis of Veterinary Disease, 4th Edition

pneumonocytes can interfere in gas exchange and cause hypoxemia. In uncomplicated cases, type II pneumonocytes eventually differentiate into type I pneumonocytes, thus completing the last stage of alveolar repair.

Type I pneumonocytes are one of the three structural components of the blood-air barrier, so when these epithelial cells are damaged there is an increase in alveolar capillary permeability and transient leakage of plasma fluid, proteins, and fibrin into the alveolar lumen. Under normal circumstances, these fluids are rapidly cleared from the alveolus by alveolar and lymphatic absorption, and necrotic pneumonocytes (type I) and fibrin strands are phagocytosed and removed by pulmonary alveolar macrophages. When there is persistent and severe injury, fibroblasts may proliferate in the alveolar walls (alveolar interstitium) causing alveolar fibrosis, whereas in other forms of severe injury, fibroblasts actively migrate from the interstitium into the alveolar spaces, causing intraalveolar fibrosis. These two types of alveolar fibrosis are most commonly seen in toxic and allergic pulmonary diseases, which have a devastating effect of lung function.

On a minute-to-minute basis, the pulmonary defense mechanisms deal effectively with noxious stimuli and mild tissue injury without the need for an inflammatory response. However, if normal defense mechanisms are ineffective or insufficient (overwhelmed), the inflammatory process is rapidly turned on as a second line of defense.

### 9.2.3.7

#### GENERAL ASPECTS OF LUNG INFLAMMATION

In the past two decades, an information explosion has increased the overall understanding of pulmonary inflammation, with so many proinflammatory and antiinflammatory mediators described to date that it would be impossible to review them all here (see [Chapter 3](#)).

Pulmonary inflammation is a highly regulated process that involves a complex interaction between cells imported from the blood (neutrophils, eosinophils, mast cells, and lymphocytes) and pulmonary cells (type I and II pneumonocytes and endothelial, Clara, and stromal interstitial cells). Blood-borne leukocytes, platelets, and plasma proteins are brought into the areas of inflammation by an elaborate network of chemical signals emitted by pulmonary cells and resident leukocytes. Long-distance communication between pulmonary cells and blood cells is largely done by soluble cytokines; once in the lung, imported leukocytes communicate with pulmonary and vascular cells through adhesion and other inflammatory molecules. The best known inflammatory mediators are the complement system (C3a, C3b, C5a), coagulation factors (factors V, VII), arachidonic acid metabolites (leukotrienes and prostaglandins), cytokines (interleukins, monokines, chemokines), adhesion molecules (ICAM, VCAM), enzymes and enzyme inhibitors (elastase, antitrypsin), oxygen metabolites ( $O_2^{\cdot -}$ ,  $OH^{\cdot}$ ,  $H_2O_2$ ), antioxidants (glutathione), and nitric oxide ([Table 9-3](#)).

Acting in concert, these and many other molecules send positive or negative signals to initiate, maintain, and hopefully resolve the inflammatory process without causing injury to the lung.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 9-3 Main Chemical Mediators Involved in Pulmonary Inflammation

Name	Source	Function in the Lung
Histamine	Mast cells, basophils, monocytes	Increase vascular permeability, pain
Prostaglandins and leukotrienes	Cell membranes	Increase permeability, platelet aggregation, vasoconstriction or vasodilation, lung edema, pain
L-selectin	Neutrophils, monocytes	Leukocyte attachment and migration, homing to areas of pulmonary inflammation
P-, E-selectins; ICAM-1, ELAM-1	Venues and capillary endothelium	Leukocyte attachment and migration to areas of pulmonary inflammation
IL-1	Alveolar macrophages	Endothelial-leukocyte adherence (ELAMs), leukocyte chemotaxis
IL-6	Macrophages	Lymphocyte and fibroblast activation in the lung; down-regulates TNF and reduces inflammation
IL-8	Macrophages, fibroblasts	Leukocyte and lymphocyte chemotaxis
IL-9	Macrophages, alveolar cells	Decreases cytokine production in pulmonary alveolar macrophages
Tumor necrosis factor (TNF- $\alpha$ )	Alveolar macrophages	Endothelial-leukocyte attachment (ELAMs), vascular permeability, lung edema; fever and acute-phase proteins, apoptosis
Eotaxin and IL-5	Lymphocytes	Eosinophil chemotaxis, airway eosinophilia, asthma, pulmonary allergies
Epithelial secretory proteins	Type I and II pneumonocytes, Clara cells	Modulation of lung inflammation; regulation of fibroblasts, fibrosis, and NO
Surfactant A, B (collectins)	Type II pneumonocyte and Clara cells	Chemotaxis, phagocytosis, immunomodulation, regulation of NO
Nitric oxide (NO)	Pneumonocytes, macrophages, endothelium	Decreases cytokine production in pulmonary alveolar macrophages; modulation of apoptosis
Transforming growth factors (TGF- $\alpha$ and TGF- $\beta$ )	Pneumonocytes, macrophages	Lung remodeling, deposition of connective tissue, fibrosis

*ELAM*, Endothelial adhesion molecule; *ICAM*, intercellular adhesion molecule; *IL*, interleukin.

Pulmonary macrophages (alveolar, intravascular, and interstitial), which have an immense biologic armamentarium, are the single most important effector cell and source of cytokines for all stages of pulmonary inflammation. These all-purpose phagocytic cells modulate the recruitment and trafficking of blood-borne leukocytes in the lung through the secretion of chemokines (Table 9-3).

Before reviewing how inflammatory cells are recruited in the lungs, three significant features in pulmonary injury must be remembered: (1) Leukocytes can exit the vascular system through the alveolar capillaries, unlike in other tissues, where postcapillary venules are the sites of leukocytic diapedesis (extravasation); (2) the intact lung contains within alveolar capillaries a large pool of resident leukocytes (marginal pool); and (3) additional neutrophils are sequestered within alveolar capillaries within minutes of local or systemic inflammatory response. These three pulmonary idiosyncrasies, along with the enormous length of the capillary network in the lung, explain why recruitment and migration of leukocytes into alveolar spaces develops so rapidly. Experimental studies with aerosols of endotoxin or gram-negative bacteria have shown that within minutes of exposure, there is a significant increase in capillary leukocytes, and by 4 hours the entire alveolar lumen is filled with neutrophils. Not surprisingly, the BAL fluid collected from patients with acute pneumonia contains large amounts of inflammatory mediators such as TNF- $\alpha$ , IL-1, and IL-8. Also, the capillary endothelium of patients with acute pneumonia has increased “expression” of adhesion molecules, which facilitate the migration of leukocytes from capillaries into the alveolar interstitium and from there into

## Pathologic Basis of Veterinary Disease, 4th Edition

---

the alveolar lumen. In allergic pulmonary diseases, eotaxin and IL-5 are primarily responsible for recruitment and trafficking of eosinophils in the lung ([Table 9-3](#)).

Movement of plasma proteins into the pulmonary interstitium and alveolar lumen is a common but poorly understood phenomenon in pulmonary inflammation. Leakage of fibrinogen and plasma proteins can be caused by direct physical damage to the blood-air barrier. This leakage is also promoted by some types of cytokines that enhance procoagulant activity, whereas others reduce fibrinolytic activity. Excessive exudation of fibrin into the alveoli is particularly common in ruminants and pigs. The fibrinolytic system plays a major role in the resolution of pulmonary inflammatory diseases. In some cases, excessive plasma proteins leaked into alveoli mix with necrotic type I pneumonocytes and pulmonary surfactant, forming microscopic eosinophilic bands (membranes) along the lining of alveolar septa. These membranes, known as “hyaline membranes,” are found in specific types of pulmonary diseases, particularly in ARDS, and in cattle with acute interstitial pneumonias such as bovine pulmonary edema and emphysema and extrinsic allergic alveolitis ([Fig. 9-35](#)).

506

507

In the last few years, nitric oxide has been identified as a major regulatory molecule of inflammation in a variety of tissues, including the lung. Produced locally by macrophages, pulmonary endothelium, and pneumonocytes, nitric oxide regulates the vascular and bronchial tone, modulates the production of cytokines, controls the recruitment and trafficking of neutrophils in the lung, and switches on/off genes involved in inflammation and immunity. Experimental work has also shown that pulmonary surfactant up-regulates the production of nitric oxide in the lung, supporting the current view that pneumonocytes are also pivotal in amplifying and down-regulating the inflammatory and immune responses in the lung ([Table 9-3](#)).

As the inflammatory process becomes chronic, the types of cells making up cellular infiltrates in the lung change from mainly neutrophils to largely mononuclear cells. This shift in cellular composition is accompanied by an increase in specific cytokines, such as IL-4, interferon- $\gamma$  (IFN- $\gamma$ ), and interferon-inducible protein (IP-10), which are chemotactic for lymphocytes and macrophages. Under appropriate conditions, these cytokines activate T lymphocytes, regulate granulomatous inflammation, and induce the formation of multinucleated giant cells, such as in mycobacterial infections.

Inflammatory mediators locally released from inflamed lungs also have a biologic effect in other tissue. For instance, pulmonary hypertension and right side heart failure (cor pulmonale) often follows chronic alveolar inflammation, not only as a result of increased pulmonary blood pressure but also from the effect of inflammatory mediators on the contractibility of smooth muscle of the pulmonary and systemic vasculature. Cytokines, particularly TNF- $\alpha$ , which are released during inflammation are associated, both as cause and effect, with the systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis with multiple organ dysfunction, and septic shock (cardiopulmonary collapse).

As it occurs in any other sentinel system where many biologic promoters and inhibitors are involved (coagulation, the complement and immune systems), the inflammatory cascade could go into an “out-of-control” state, causing severe damage to the lungs. ARDS, extrinsic allergic alveolitis, pulmonary fibrosis, and asthma are archetypical diseases that ensue from an uncontrolled production and release of cytokines.

As long as alveolar injury is transient and there is no interference with the normal host response, the entire process of injury, degeneration, necrosis, inflammation, and repair can occur in less than 1 week. On the other hand, when alveolar injury becomes persistent or when the capacity of the host for repair is impaired, lesions can progress to an irreversible stage in which restoration of alveolar structure is no longer possible. In

## Pathologic Basis of Veterinary Disease, 4th Edition

---

diseases such as extrinsic allergic alveolitis, the constant release of proteolytic enzymes and free radicals by phagocytic cells perpetuates alveolar damage in a vicious circle. In other cases, such as in paraquat toxicity, the magnitude of alveolar injury can be so severe that type II pneumonocytes, basement membranes, and alveolar interstitium are so disrupted that the capacity for alveolar repair is lost. Fibronectins and transforming growth factors released from macrophages and other mononuclear cells at the site of chronic inflammation regulate the recruitment, attachment, and proliferation of fibroblasts. In turn, these cells synthesize and release considerable amounts of extracellular matrix (collagen, elastic fibers, proteoglycans), eventually leading to fibrosis and total obliteration of normal alveolar architecture. In summary, in diseases in which there is chronic and irreversible alveolar damage, lesions invariably progress to a stage of terminal alveolar fibrosis.

9.2.3.8

### CLASSIFICATION OF PNEUMONIAS

Few subjects in veterinary pathology have caused so much debate as the classification of pneumonias. Historically, pneumonias in animals have been classified or named based on (1) presumed cause, with names such as viral pneumonia, *Pasteurella* pneumonia, distemper pneumonia, verminous pneumonia, chemical pneumonia, and hypersensitivity pneumonitis; (2) type of exudation, with names such as suppurative pneumonia, fibrinous pneumonia, and pyogranulomatous pneumonia; (3) morphologic features, with names such as gangrenous pneumonia, proliferative pneumonia, and embolic pneumonia; (4) distribution of lesions, with names such as focal pneumonia, cranioventral pneumonia, diffuse pneumonia, and lobar pneumonia; (5) epidemiologic attributes, with names such as enzootic pneumonia, contagious bovine pleuropneumonia, and pneumonic manheimiosis pneumonia; (6) geographic regions, with names such as Montana progressive pneumonia; and finally, (7) miscellaneous attributes, with names such as atypical pneumonia, cuffing pneumonia, progressive pneumonia, aspiration pneumonia, pneumonitis, farmer's lung, and extrinsic allergic alveolitis. Until a universal and systematic nomenclature for animal pneumonias are established, veterinarians should be acquainted with this heterogeneous list of names and should be well aware that one disease may be known by different names. In pigs, for instance, enzootic pneumonia, virus pneumonia, and *Mycoplasma* pneumonia all refer to the same disease caused by *Mycoplasma hyopneumoniae*.

507

508

The word *pneumonitis* has been used by some as a synonym for pneumonia; however, others have restricted this term to chronic proliferative inflammation generally involving the alveolar interstitium and with little or no evidence of exudate. In this chapter, the word *pneumonia* is used for any inflammatory lesion in the lungs, regardless of whether it is exudative or proliferative, alveolar, or interstitial.

Pneumonias in domestic animals can be classified based on texture, distribution, appearance and exudation into four morphologically distinct types: bronchopneumonia, interstitial pneumonia, embolic pneumonia, and granulomatous pneumonia. By using this classification, it is possible to predict with some degree of certainty the likely cause (virus, bacteria, fungi, parasites), routes of entry (aerogenous versus hematogenous), and possible sequelae to which each of these types of pneumonia may progress if the animal were to survive. However, overlapping of these four types of pneumonias is possible, and sometimes two morphologic types may be present in the same lung.

## Pathologic Basis of Veterinary Disease, 4th Edition

Table 9-4 Morphologic Types of Pneumonias in Domestic Animals

Type of Pneumonia	Port of Entry (e.g., Pathogens)	Distribution of Lesions	Texture of Lung	Grossly Visible Exudate	Disease Example	Common Pulmonary Sequelae
Bronchopneumonia:						
Suppurative (lobular)	Aerogenous (bacteria and mycoplasmas)	Cranioventral consolidation	Firm	Purulent exudate in bronchi	Enzootic pneumonia	Cranioventral abscesses, adhesions, bronchiectasis,
Fibrinous (lobar)	Aerogenous (bacteria and mycoplasmas)	Cranioventral consolidation*	Hard	Fibrin in lung and pleura	Pneumonic manheimiosis	BALT hyperplasia, "sequestra," pleural adhesions, abscesses
Interstitial pneumonia	Aerogenous or hematogenous (virus, toxin, allergen, sepsis)	Diffuse	Elastic with rib imprints	Not visible, trapped in alveolar septa	Influenza, extrinsic allergic alveolitis, PRRS, ARDS	Edema, emphysema, type II alveolar hyperplasia, alveolar fibrosis
Granulomatous pneumonia	Aerogenous or hematogenous ( <i>Mycobacteria</i> , systemic mycoses)	Multifocal	Nodular	Pyogranulomatous, caseous necrosis, calcified nodules	Tuberculosis, blastomycosis, cryptococcosis	Dissemination of infection to lymph nodes and distant organs
Embolic pneumonia	Hematogenous (septic emboli)	Multifocal	Nodular	Purulent foci surrounded by hyperemia	Vegetative endocarditis, ruptured liver abscess	Abscesses randomly distributed in all pulmonary lobes

ARDS, Adult respiratory distress syndrome; BALT, bronchial associated lymphoid tissue; PRRS, Porcine reproductive and respiratory syndrome.

\* Porcine pleuropneumonia is an exception because it often involves the caudal lobes.

The criteria used to classify pneumonias into bronchopneumonia, interstitial pneumonia, embolic pneumonia, and granulomatous pneumonia are based on morphologic changes, including distribution, texture, color, and appearance of the affected lungs (Table 9-4). According to distribution of the inflammatory lesions in the lungs, pneumonias can be cranioventral, as in most bronchopneumonias; multifocal, as in embolic pneumonias; diffuse, as in interstitial pneumonias; or locally extensive, as in granulomatous pneumonias (Fig. 9-47). Texture of pneumonic lungs can be firmer or harder (bronchopneumonias), more elastic (rubbery) than normal lungs (interstitial pneumonias), or have a nodular feeling (granulomatous pneumonias). Describing in words the palpable difference between the texture of a normal lung compared with the firm or hard texture of a consolidated lung can be a difficult undertaking. An analogy illustrating this difference based on touching the parts of the face with the tip of your finger has been advocated by some pathologists. The texture of a normal lung is comparable to the texture of the center of the cheek. Firm consolidation is comparable to the texture of the tip of the nose, and hard consolidation is comparable to the texture of the forehead. The term *consolidation* is frequently used to describe a firm or hard lung filled with exudate.

508

509

**Fig. 9-47 Schematic diagram of the patterns of pneumonia.** **A**, Normal lung. **B**, Suppurative bronchopneumonia showing cranioventral consolidation and accentuated lobular pattern. **C**, Fibrinous bronchopneumonia showing cranioventral consolidation and fibrin on pleura (*yellow*). **D**, Interstitial pneumonia showing diffuse distribution and rib imprints in all pulmonary lobes. **E**, Embolic pneumonia showing multifocal distribution involving all pulmonary lobes. **F**, Granulomatous pneumonia showing multifocal nodules in all pulmonary lobes. (*A through F, Redrawn with permission from Dr. A. López, Atlantic Veterinary College.*)

Changes in the appearance of pneumonic lungs include abnormal color, presence of nodules or exudate, fibrinous or fibrous adhesions, and presence of rib imprints on serosal surfaces (Fig. 9-47). On cut surfaces, pneumonic lungs may have exudate, hemorrhage, edema, necrosis, abscesses, bronchiectasis, granulomas or pyogranulomas, and fibrosis, depending on the stage.

Palpation and careful observation of the lungs are essential in the diagnosis of pneumonia. (For details, see Examination of the Respiratory Tract, Postmortem.)

### 9.2.3.8.1

#### Bronchopneumonia

*Bronchopneumonia* refers to a particular type of pneumonia in which injury and the inflammatory process take place primarily in the bronchial, bronchiolar, and alveolar lumens. Bronchopneumonia is undoubtedly the most common type of pneumonia seen in domestic animals and is, with few exceptions,

## Pathologic Basis of Veterinary Disease, 4th Edition

characterized by cranioventral consolidation of the lungs (Fig. 9-48). The reason why bronchopneumonias in animals are almost always restricted to the cranioventral portions of the lungs is not well understood. Possible factors contributing to this topographic selectivity within the lungs include (1) gravitational sedimentation of the exudate; (2) greater deposition of infectious organisms; (3) inadequate defense mechanisms; (4) reduced vascular perfusion; (5) shortness and abrupt branching of airways; and (6) regional differences in ventilation.

The term *cranioventral* of veterinary anatomy is the equivalent of “anterosuperior” of human anatomy. The latter is defined as “in front (ventral) and above (cranial).” Thus applied to the lung of animals, “cranioventral” means the ventral portion of the cranial lobe. However, by common usage in veterinary pathology, the term *cranioventral* used to describe the location of lesions in pneumonias has come to mean “cranial and ventral.” Thus it includes pneumonias affecting not only the ventral portion of the cranial lobe (true cranioventral) but also those cases in which the pneumonia has involved the ventral portions of adjacent lung lobes—initially the middle, and then caudal on the right and the caudal lobe on the left side.

509

510

**Fig. 9-48 Suppurative bronchopneumonia, enzootic pneumonia, lung, calf.** **A**, Cranioventral consolidation (C) of the lung involves approximately 40% of pulmonary parenchyma. Most of the caudal lung is normal (N). **B**, Cut surface. Consolidated lung is dark red to mahogany (C), and a major bronchus contains purulent exudate (arrow). N, Normal. (A and B, Courtesy Ontario Veterinary College.)

Bronchopneumonias are generally caused by bacteria and mycoplasmas, by bronchoaspiration of feed or gastric contents, or by improper tubing. As a rule, the pathogens causing bronchopneumonias arrive in the lungs via inspired air (aerogenous), either from infected aerosols or from the nasal flora. Before establishing infection, pathogens must overwhelm or evade the pulmonary defense mechanism. The initial injury in bronchopneumonias is centered on the mucosa of bronchioles; from there, the inflammatory process can spread downward to distal portions of the alveoli and upward to the bronchi. Typically for bronchopneumonias, the inflammatory exudates collect in the bronchial, bronchiolar, and alveolar lumina leaving the alveolar interstitium reasonably unchanged. Through the pores of Kohn, the lesions and exudate can spread centripetally to adjacent alveoli until part or all of the alveoli in an individual lobule are involved. If the inflammatory process cannot control the inciting cause of injury, the lesions spread

## Pathologic Basis of Veterinary Disease, 4th Edition

---

rapidly from lobule to lobule through alveolar pores and destroyed alveolar walls, until an entire lobe or large portion of a lung is involved. The lesion tends to spread centrifugally, with the older lesions being in the center, and exudate can be coughed up and then aspirated into other lobules, where the inflammatory process starts again.

At the early stages of bronchopneumonia, the pulmonary vessels are engorged with blood (active hyperemia) and the bronchi, bronchioles, and alveoli contain some fluid (permeability edema). In cases in which pulmonary injury is mild to moderate, cytokines locally released in the lung cause rapid recruitment of neutrophils and alveolar macrophages into bronchioles and alveoli (Fig. 9-49). When pulmonary injury is much more severe, proinflammatory cytokines induce more pronounced vascular changes by further opening endothelial gaps, thus increasing vascular permeability resulting in fibrinous exudates and sometimes hemorrhage in the alveoli. Alterations in permeability can be further exacerbated by structural damage to pulmonary capillaries and vessels directly caused by microbial toxins. The final result of these functional and structural changes is that blood vessels become notably permeable and allow substantial leakage of plasma fluid and proteins (fibrinogen) into the alveoli. Filling of alveoli, bronchioles, and small bronchi with inflammatory exudate progressively obliterates airspaces, and as a consequence of this process, portions of severely affected (consolidated) lungs sink to the bottom of the container when placed in fixative. The replacement of air by exudate also changes the texture of the lungs, and depending on the severity of bronchopneumonia, the texture varies from firmer to harder than normal.

Fig. 9-49 **Suppurative bronchopneumonia, lung, pig.** **A**, Note the bronchiole plugged with purulent exudate. The alveoli are filled with leukocytes and some edematous fluid. H&E stain. **B**, Schematic diagram of acute bronchiolitis. Note the neutrophils exiting the submucosal capillaries (leukocyte adhesion cascade; see [Chapter 3](#)) and moving into the walls of the bronchioles and then into the bronchiolar lumen. (**A and B**, Courtesy Dr. A. López, Atlantic Veterinary College.)

The term *consolidation* is used when the texture of pneumonic lung becomes firmer or harder than normal as a result of loss of airspaces because of exudation and atelectasis. (For details, see the discussion of lung texture in Classification of Pneumonias). Inflammatory consolidation of lungs has been referred to in the past as “hepatization,” because the affected lung had the appearance and texture of liver. The process was referred to as “red hepatization” in acute cases in which there was notable active hyperemia with little exudation of neutrophils; conversely, the process was referred to as “gray hepatization” in those chronic cases in which hyperemia was no longer present, but there was abundant exudation of neutrophils and macrophages. This terminology, although used and applicable to human pneumonias, is rarely used in veterinary medicine primarily because the evolution of pneumonic processes in animals does not necessarily follow the red-to-gray hepatization pattern. 510 511

Bronchopneumonias can be arbitrarily subdivided into suppurative bronchopneumonia if the exudate is predominantly composed of neutrophils, and fibrinous bronchopneumonia if fibrin is the predominant component of the exudate (Table 9-4). It is important to note that some pathologists use the term *fibrinous pneumonia* or *lobar pneumonia* as a synonym for fibrinous bronchopneumonia, and *bronchopneumonia* or *lobular pneumonia* as a synonym for suppurative bronchopneumonia. Currently, the term *bronchopneumonia* is widely used for both suppurative and fibrinous consolidation of the lungs, because both forms of inflammation have essentially the same pathogenesis in which the pathogens reach the lung by the aerogenous route, injury occurs initially in the bronchial and bronchiolar regions, and the inflammatory process extends centrifugally deep into the alveoli. It must be emphasized that it is the severity of pulmonary injury that largely determines whether bronchopneumonia becomes suppurative or fibrinous. In some instances, however, it is difficult to discriminate between suppurative and fibrinous bronchopneumonia because both types can coexist (fibrinosuppurative bronchopneumonia), and one type can progress to the other.

Suppurative bronchopneumonia is characterized by cranioventral consolidation of lungs (Figs. 9-47 and 9-48), with typical presence of purulent or mucopurulent exudate in the airways. This exudate can be best demonstrated by expressing intrapulmonary bronchi, thus forcing exudate out of the bronchi (Fig. 9-48). The inflammatory process in suppurative bronchopneumonia is generally confined to individual lobules, and, as a result of this distribution, the lobular pattern of the lung becomes notably emphasized. This pattern is particularly obvious in cattle and pigs because these species have prominent lobulation of the lungs. The gross appearance often resembles an irregular checkerboard because of an admixture of normal and abnormal (consolidated) lobules (Fig. 9-48). Because of this typical lobular distribution, suppurative bronchopneumonias are also referred to as lobular pneumonias.

Different inflammatory phases occur in suppurative bronchopneumonia where the color and appearance of consolidated lungs varies considerably depending on the virulence of offending organisms and chronicity of the lesion. The typical phases of suppurative bronchopneumonia could be summarized as follows: During the first 12 hours when bacteria are rapidly multiplying, the lungs become hyperemic and edematous. Soon after neutrophils start filling the airways and by 48 hours the parenchyma starts to consolidate and becomes firm in texture. Three to 5 days later, hyperemic changes are less obvious, but the bronchial, bronchiolar, and alveolar spaces continue to fill with neutrophils and macrophages, and the affected lung sinks when placed in formalin. At this stage, the affected lung has a gray-pink color, and on cut surface purulent exudate can be expressed from bronchi. In favorable conditions where the infection is under control of the host defense mechanisms, the inflammatory processes begin to regress, a phase known as resolution. Complete resolution in favorable conditions could take 1 to 2 weeks. In animals in which the lung infection cannot be rapidly contained, inflammatory lesions can progress into a chronic phase. Around 7 to 10 days after infection, the lungs become pale gray and take a “fish flesh” appearance.

## Pathologic Basis of Veterinary Disease, 4th Edition

---

This appearance is the result of purulent and catarrhal inflammation, obstructive atelectasis, mononuclear cell infiltration, lymphoid hyperplasia, and early fibrosis. Complete resolution is unusual in chronic bronchopneumonia, and lung scars, such as fibrosis, bronchiectasis, atelectasis, adhesions, and abscesses, may remain unresolved for a long time. “Enzootic pneumonias” of ruminants and pigs are typical examples of chronic suppurative bronchopneumonias.

Microscopically, suppurative bronchopneumonias are characterized by abundant neutrophils, macrophages, and cellular debris within the lumen of bronchi, bronchioles, and alveoli (Fig. 9-49). Recruitment of leukocytes is promoted by cytokines, complement, and other chemotactic factors that are released in response to alveolar injury or by the chemotactic effect of bacterial toxins, particularly endotoxin. In most severe cases, purulent or mucopurulent exudates completely obliterate the entire lumen of bronchi, bronchioles, and alveoli.

If suppurative bronchopneumonia is merely the response to a transient pulmonary injury or a mild infection, lesions resolve uneventfully. Within 7 to 10 days, cellular exudate can be removed from the lungs via the mucociliary escalator, and complete resolution may take place within 4 weeks. In other cases, if injury or infection is persistent, suppurative bronchopneumonia can become chronic with goblet cell hyperplasia, an important component of the inflammatory process. Depending on the proportion of pus and mucus, the exudate in chronic suppurative bronchopneumonia varies from mucopurulent to mucoid. A mucoid exudate is found in the more chronic stages when the consolidated lung has a “fish flesh” appearance.

511

512

Hyperplasia of BALT is another change commonly seen in chronic suppurative bronchopneumonias; it appears grossly as conspicuous white nodules (cuffs) around bronchial walls (cuffing pneumonia). This hyperplastic change merely indicates a normal reaction of lymphoid tissue to infection. Further sequelae of chronic suppurative bronchopneumonia include bronchiectasis (Fig. 9-46), pulmonary abscesses, and pleural adhesions (from pleuritis), and atelectasis and emphysema from completely or partially obstructed bronchi or bronchioles (e.g., bronchiectasis).

Clinically, suppurative bronchopneumonias can be acute and fulminating, but are often chronic, depending on the etiologic agent, stressors affecting the host, and immune status. The most common pathogens causing suppurative bronchopneumonia in domestic animals include *Pasteurella multocida*, *Bordetella bronchiseptica*, *Arcanobacterium (Actinomyces) pyogenes*, *Streptococcus* spp., *Escherichia coli*, and several species of mycoplasmas. Most of these organisms are secondary pathogens requiring a preceding impairment of the pulmonary defense mechanisms to colonize the lungs and establish an infection. Suppurative bronchopneumonia can also result from aspiration of bland material (e.g., milk). Pulmonary gangrene may ensue when the bronchopneumonic lung is invaded by saprophytic bacteria.

Fibrinous bronchopneumonia is similar to suppurative bronchopneumonia except that the predominant exudate is fibrinous rather than neutrophilic. With only a few exceptions, fibrinous bronchopneumonias also have a cranioventral distribution (Figs. 9-47, C and 9-50). However, exudation is not restricted to the boundaries of individual pulmonary lobules, as is the case in suppurative bronchopneumonias. Instead the inflammatory process in fibrinous pneumonias involves numerous contiguous lobules and the exudate moves quickly through pulmonary tissue until the entire pulmonary lobe is rapidly affected. Because of the involvement of the entire lobe and pleural surface, fibrinous bronchopneumonias are also referred to as lobar pneumonias or pleuropneumonias. In general terms, fibrinous bronchopneumonias are the result of more severe pulmonary injury and thus are more life threatening than suppurative bronchopneumonias. Even in cases in which fibrinous bronchopneumonia involves 30% or less of the total area, clinical signs and death can occur as a result of severe toxemia.

**Fig. 9-50 Fibrinous bronchopneumonia (pleuropneumonia), right lung, steer.** **A**, The pneumonia has a cranioventral distribution that extends into the middle and caudal lobes and affects approximately 80% of the lung parenchyma. The lung is firm, swollen, and covered with yellow fibrin (\*). The dorsal portion of the caudal lung is normal (N). **B**, Cut surface. Affected parenchyma appears dark and hyperemic as compared with a normal (N) lung. This type of lesion is typical of *Mannheimia haemolytica* infection in cattle (shipping fever). (**A and B**, Courtesy Ontario Veterinary College.)

The gross appearance of fibrinous bronchopneumonia depends on the age and severity of the lesion and on whether the lung is observed externally or on a cut surface. Externally, early stages of fibrinous bronchopneumonias are characterized by severe congestion and hemorrhage, giving the affected lungs a characteristically intense red discoloration. A few hours later, fibrin starts to accumulate on the pleural surface, giving the pleura a ground glass appearance and eventually forming plaques of fibrinous exudate over a red, dark lung (Fig. 9-50). At this stage, a yellow fluid starts to accumulate in the thoracic cavity. The color of fibrin deposited over the pleural surface is also variable depending on the proportion of red blood cells, hemoglobin, and leukocytes. It can be yellow when the exudate is formed primarily by fibrin, tan when fibrin is mixed with blood, and gray when a large number of leukocytes are part of the fibrinous plaque. Because of the tendency of fibrin to deposit on the pleural surface, some pathologists use the term *pleuropneumonia* as a synonym for fibrinous bronchopneumonia.

On the cut surface, early stages of fibrinous bronchopneumonia appear as simple red consolidation (Fig. 9-50). In more advanced cases (24 hours), fibrinous bronchopneumonia is generally accompanied by notable dilation and thrombosis of lymph vessels and edema of interlobular septa. This distention of the interlobular septa gives affected lungs a typical marbled appearance. Distinct focal areas of coagulative necrosis in the pulmonary parenchyma are also common in fibrinous bronchopneumonia, such as in shipping fever pneumonia and contagious bovine pleuropneumonia. In animals that survive the early stage

of fibrinous bronchopneumonia, pulmonary necrosis often develops into pulmonary “sequestra,” which are isolated pieces of necrotic lung encapsulated by connective tissue. Pulmonary sequestra result from extensive necrosis of lung tissue caused either by severe ischemia or by the effect of necrotizing toxins released by pathogenic bacteria. Sequestra in veterinary pathology should not be confused with “bronchopulmonary sequestration,” a term used in human pathology to describe a congenital malformation in which whole lobes or parts of the lung develop without normal connections to the airway or vascular systems.

Microscopically, in the initial stage of fibrinous bronchopneumonia, there is massive exudation of plasma proteins into the bronchioles and alveoli, and as a result most of the airspaces become obliterated by fluid and fibrin. Leakage of fibrin and fluid into alveolar lumina is because of extensive disruption of the integrity and increased permeability of the blood-air barrier. Fibrinous exudates can move from alveolus to alveolus through the pores of Kohn. Because fibrin is chemotactic for neutrophils, these types of leukocytes are always present a few hours after the onset of fibrinous inflammation. As inflammation progresses (3 to 5 days), fluid exudate is gradually replaced by a fibrinocellular exudates composed of fibrin, neutrophils, macrophages, and necrotic debris (Fig. 9-51). In chronic cases (after 7 days), there is notable fibrosis of the interlobular septa and pleura.

In contrast to suppurative bronchopneumonia, fibrinous bronchopneumonia rarely resolves completely, thus leaving noticeable scars in the form of pulmonary fibrosis and pleural adhesions. The most common sequelae found in animals surviving an acute episode of fibrinous bronchopneumonia include bronchiolitis obliterans, in which organized exudate becomes attached to the bronchiolar lumen; gangrene, when saprophytic bacteria colonize necrotic lung; pulmonary sequestra; pulmonary fibrosis; abscesses; and chronic pleuritis with pleural adhesions. In some cases, pleuritis can be so extensive that fibrous adhesions extend onto the pericardial sac. Pathogens causing fibrinous bronchopneumonias in domestic animals include *Mannheimia* (*Pasteurella*) *haemolytica* (pneumonic mannheimiosis), *Histophilus somni* (formerly *Haemophilus somnus*), *Actinobacillus pleuropneumoniae* (porcine pleuropneumonia), *Mycoplasma bovis*, and *Mycoplasma mycoides* ssp. *mycoides* small colony type (contagious bovine pleuropneumonia). Fibrinous bronchopneumonia and pulmonary gangrene can also be the result of bronchoaspiration of irritant materials, such as gastric contents.

---

Fulminating hemorrhagic bronchopneumonia can be caused by highly pathogenic bacteria, such as *Bacillus anthracis*. Although the lesions in anthrax are primarily related to a severe septicemia and sepsis, anthrax should always be suspected in animals with sudden death and exhibiting severe acute fibrinohemorrhagic pneumonia, splenomegaly, and multisystemic hemorrhages. Animals are considered good sentinels for anthrax in cases of bioterrorism.

### 9.2.3.8.2

#### Interstitial Pneumonia

Interstitial pneumonia refers to a particular type of pneumonia in which injury and the inflammatory process take place primarily in any of the three layers of the alveolar walls (endothelium, basement membrane, and alveolar epithelium) and the contiguous bronchiolar interstitium. This type of pneumonia is perhaps the most difficult to diagnose at necropsy and generally requires microscopic confirmation. The pathogenesis of interstitial pneumonia is complex and can result from aerogenous injury to the alveolar epithelium (type I and II pneumonocytes) or from hematogenous injury to the alveolar capillary endothelium or alveolar basement membrane.
